$$NH_2CONHCOONa \rightarrow NaOCN + NH_3 + CO_2 \quad (5)$$

The overall reaction is the formation of two moles of sodium cyanate and one mole of ammonium carbonate from one mole of sodium carbonate and two moles of urea (Eq. 6).

$$Na_2CO_3 + 2\,H_2NCONH_2 \rightarrow 2\,NaOCN + (NH_4)_2CO_3 \quad (6)$$

The reaction is endothermic and requires strong heating above 200 °C for a prolonged period of time to reach completion. The reaction takes place in a urea melt with a high content of dispersed solids.

The product from this process has a purity of 89 – 92 %. The main impurity is excess sodium carbonate with small amounts of sodium allophanate, cyanuric acid, biuret, and urea.

Sodium Cyanate, High-Grade. Sodium cyanate with at least 95 % purity can be obtained by using technical-grade sodium cyanate and urea as starting materials. The process proceeds in the molten state, as described for potassium cyanate [7]. Because of the high melting point of the sodium cyanate, the reaction temperature must be raised to 550 – 600 °C. At these high temperatures, some cyanate decomposes to sodium cyanide, which can lead to formation of undesired byproducts and requires treatment of the wastewater. Also, the byproduct ammonia may ignite (flash point 600 °C). For these reasons, production is not without risk.

Potassium Cyanate, High-Grade. The production of potassium cyanate from potassium carbonate and urea requires reaction temperatures of 400 °C or above. The product is obtained from the reactor as a liquid, which must be solidified by cooling and ground after solidification. Since the crystalline structure of the potassium carbonate is destroyed in the melting process, the urea can reach nearly all potassium ions and convert them to potassium cyanate at a much higher rate than in the case of the technical-grade sodium salt. It is therefore easy to reach high purities above 95 %. While possible impurities like urea, biuret, cyanuric acid, and potassium allophanate are unstable at the reaction temperature and therefore are easily eliminated, the temperature is still too low to allow for significant formation of potassium cyanide.

Treatment of Byproducts. To facilitate isolation of the ammonium carbonate byproduct during the reaction, a continuous process for cyanate production is preferred to a batch process. If undesired, the ammonia in the off-gases can be burned. It is more economic to trap the ammonia by washing the gases with cold water or acid and use the resulting aqueous solution otherwise, for example, reaction with formaldehyde to produce hexamethylenetetramine.

4. Uses

A review of the chemical reactions involving cyanate salts has been published [10].

Sodium cyanate is used as such in steel hardening; potassium cyanate is used as herbicide in the onion crop. All other applications require chemical synthesis, for which sodium cyanate is often the salt of choice. In most reactions, it can be regarded as a safe alternative to phosgene chemistry. The following reactions are or have been of commercial value.

Reactions with primary or secondary amines afford monosubstituted ureas [11] (Eq. 7).

$$RNH_2 \cdot HCl + MOCN \rightarrow RNHCONH_2 + MCl \quad (7)$$

where, e.g., R = ethyl, *tert*-butyl, cyclohexyl, phenyl

Sodium and potassium cyanate behave alike. Potassium cyanate is sometimes preferred to sodium cyanate because of its higher purity and its much higher solubility in water, a popular solvent for this type of reaction. Another solvent used for this reaction is ethyl acetate. Well-known pharmaceuticals produced by this type of reaction are the antiepileptic carbamazepine and the dermatotherapeutic agent hydroxyurea. The fungicides cymoxanil, lenacil and terbacil are also produced by this type of reaction, as well as the herbicides isoproturon and diuron. The reaction of aniline and sodium cyanate yields phenylurea, an intermediate for the manufacture of certain dyestuffs.

In alkylation reactions, only sodium cyanate gives satisfactory yields (Eq. 8); potassium cyanate cannot be used.

$$RX + NaOCN \rightarrow RNCO + NaX \quad (8)$$

Suitable alkylating agents are alkyl halides or sulfates. For example, allyl isocyanate is obtained from the reaction of sodium cyanate with allyl chloride. The product trimerizes readily to form triallyl isocyanurate [12]. The reaction of dimethyl sulfate with sodium cyanate results in the formation of methyl isocyanate, an intermediate for a number of insecticides [13] mainly used for rice and sugar cane crops.

Aromatic acid chlorides can react with sodium cyanate to yield benzoylurea derivatives, a novel class of herbizides [14]. Similarly, some sulfonylureas are antidiabetic agents, and sodium cyanate can be used for their synthesis. The reaction of sodium cyanate with sulfonyl chloride gives chlorosulfonylisocyanate in situ, which can be treated further in a one-pot synthesis (Eq. 9) [15]. To obtain high yields, a sodium cyanate with a low sodium carbonate content must be used.

$$NaOCN + SO_2Cl_2 \rightarrow ClSO_2NCO + NaCl \quad (9)$$

Sodium cyanate is also used as a building block in the multistep synthesis of the herbicides carfentrazone and sulfentrazone [16].

Unique applications for potassium cyanate are rare. The major application of potassium cyanate is as an ingredient in certain steel-hardening salts for the Tufftride/Tenifer process [17].

Potassium cyanate is also used in the synthesis of Carbidopa, a drug against Parkinson's disease. The reaction of amidosulfuric acid with potassium cyanate yields potassium hydroxyureasulfonate, which has found application as a polymerization catalyst for acrylonitrile [18].

The worldwide demand for cyanate salts is in the order of 8000–10 000 t/a. Production plants exist in Japan, South Korea, India, China, and Germany. Although there are some new applications in the agrochemical field, most agrochemicals which use cyanate salts for their synthesis are being slowly replaced in Europe by other agents or losing importance because of the increased use of genetically modified crops. In India and China, however, where there is a considerable increase in chemical production for agriculture, medicine, and steelmaking, new capacities have been installed.

1. Hydrogen Cyanide

Hydrogen cyanide [74-90-8], hydrocyanic acid, prussic acid, formonitrile, HCN, M_r 27.03, is a colorless liquid with the characteristic odor of bitter almonds. Hydrogen cyanide in aqueous solution was first prepared by SCHEELE in 1782 [18]. The acid occurs naturally in combination with some glucosides, such as amygdalin.

Hydrogen cyanide is currently produced by direct reaction of alkanes with ammonia, and indirectly as a byproduct of the manufacture of acrylonitrile (by ammoxidation of propene ⟶ Acrylonitrile). Major end uses include the production of adiponitrile, methyl methacrylate, cyanuric chloride, chelating agents, sodium cyanide, and methionine and its hydroxy analogues.

1.1. Properties

Physical properties [1], [19-22]:

Melting point	–13.24 °C
Boiling point	25.70 °C
Vapor pressure	
at 0 °C	35 kPa
at 20 °C	83 kPa
at 50 °C	250 kPa
Enthalpy of formation (HCN liquid), ΔH	3910 kJ/kg
Critical temperature	183.5 °C
Critical density	0.20 g/cm^3
Critical pressure	5 MPa (50 bar)
Density (20 °C)	0.687 g/cm^3
Specific heat, liquid (20 °C)	2630 J kg^{-1} K^{-1}
Specific heat, gas (25 °C)	1630 J kg^{-1} K^{-1}
Heat of fusion	310 kJ/kg
Heat of vaporization	935 kJ/kg
Heat of polymerization	–1580 kJ/kg
Explosive range in air	5.5 – 46.5 vol %
Flash point	–17.8 °C
Ignition temperature	535 °C
Dynamic viscosity, η (20 °C)	0.192 mPa · s
Surface tension (20 °C)	18.33 mN/m
Dielectric constant	
at 0 °C	158.1
at 20 °C	114.9
Dissociation constant	
aqueous solution, pK (20 °C)	9.36

As a result of its high dielectric constant, HCN has acquired some importance in preparative chemistry as a nonaqueous, ionizing solvent [23].

Chemical Properties. Some comprehensive reviews on hydrogen cyanide and cyanogen compounds have been published [1-3]. The acid occurs only in the nitrile form. Although isomeric isonitrile HNC has been detected in interstellar space, all efforts to isolate this compound have failed. As the nitrile of formic acid, HCN undergoes many typical nitrile reactions. For example, hydrogen cyanide can be hydrolyzed to formic acid by aqueous sulfuric acid or hydrogenated to methylamine. Hydrogen cyanide adds to carbon – carbon double bonds and forms cyanohydrins with carbonyl groups of aldehydes or ketones. The most important uses of this type are in the manufacture of acetone cyanohydrin (an intermediate in the production of methyl methacrylate) and in the production of adiponitrile from butadiene and hydrogen cyanide. Another example is the multistep synthesis of amino acids via hydantoins. Hydrogen cyanide can be oxidized by air over silver or gold catalysts at 300 – 650 °C to yield cyanic acid (HOCN) and cyanogen $(CN)_2$ in an approximate 2 / 1 ratio.

The reaction of hydrogen cyanide with chlorine gives cyanogen chloride (see Section Production). For industrial purposes, the latter compound is usually directly trimerized to cyanuric chloride, the starting material for the chemistry of *s*-triazines.

In the presence of oxygen or air, hydrogen cyanide burns with a very hot flame. For the reaction

$$2\,HCN + 1.5\,O_2 \rightarrow N_2 + 2\,CO + H_2O$$

the heat of formation is calculated to be –723.8 kJ/mol and the adiabatic flame temperature is 2780 °C. Pure liquid or gaseous HCN is inert to most metals and alloys such as aluminum, copper, silver, zinc, and brass. At higher temperatures (> 600 °C), the acid reacts with metals that can form carbides and nitrides (titanium, zirconium, molybdenum, and tungsten).

Pure liquid hydrogen cyanide has a tendency to polymerize to brown-black, amorphous polymers, commonly called azulmic acid [26746-21-4]. The reaction is accelerated by basic conditions, higher temperature, UV light, and the presence of radicals. Since the decomposition is exothermic, the polymerization reaction is autocatalytic and can proceed with explosive violence to form the HCN dimer iminoacetonitrile [1726-32-5] and the HCN tetramer diaminomaleonitrile [1187-42-4] as intermediates [24], [25]. Both compounds are presumed to be important in the evolution of life, and cyano compounds may play a role in prebiotic syntheses [26], [27]. In the liquid phase, hydrogen cyanide is stabilized by the presence of small amounts of acids (0.1 wt % H_3PO_4, 1 – 5 % HCOOH or CH_3COOH) or 0.2 wt % SO_2 in the gas phase.

The HCN – H_2O System. At 25 °C, hydrogen cyanide is miscible with water in all ratios. The solution is a weak acid, with a dissociation constant of the same order of magnitude as amino acids. The relation between total cyanide concentration ($c_{HCN} + c_{CN^-}$) and dissociated cyanide (c_{CN^-}) in a dilute aqueous solution, as a function of pH, is illustrated in Figure 1.

Figure 1. HCN/CN^- equilibrium as a function of pH

Figure 2 shows the liquid – vapor equilibrium diagram at atmospheric pressure. Because of the high HCN partial vapor pressure it is difficult to separate the acid from a gas mixture by absorption in water, which is an important consideration for industrial practice [28].

Figure 2. Liquid – vapor diagram of the system H_2O – HCN at atmospheric pressure

The stability of hydrogen cyanide solutions depends on the degree of dilution: at concentrations below 0.1 mol/L HCN, the acid is stable; addition of traces of acid prevents decomposition. Like pure HCN, the exothermic polymerization of an aqueous solution is accelerated by the presence of alkali. In addition to azulmic derivatives, small amounts of amino acids and purine bases are formed. This fact is of some importance to biological chemistry. The C≡N triple bond is hydrolyzed by strong alkali or acid to give formic acid and ammonia. Higher temperatures or hydrothermal conditions favor these reactions.

1.2. Production [1], [29], [30]

Hydrogen cyanide can be produced when sufficient energy is supplied to any system containing the elements hydrogen, nitrogen, and carbon. Generally, only processes starting from hydrocarbons and ammonia are of economic importance today; however, the production of hydrogen cyanide from formamide [31] is carried out in a plant at Ludwigshafen, Germany and since 1997 in a plant in Niigata, Japan. Alternative raw materials such as methanol, carbon, or carbon monoxide [32-41] are of interest since the 1980s. The ammoxidation of methanol to HCN is performed in Japan in a 10 000 – 15 000 t/a plant.

These routes can compete with conventional technology given specific site conditions. The reaction of hydrocarbons with ammonia

$$C_xH_{2x+2} + xNH_3 \rightarrow xHCN + 2\cdot(2x+1)H_2$$

is highly endothermic and needs a continuous heat supply. The means of providing this energy requirement are manifold and characteristic of the different processes [43]. Direct microwave heating of the catalyst has been developed for small-scale local synthesis of HCN [44]. The main processes currently used to make hydrogen cyanide: the Andrussow ammoxidation process, which involves the reaction of ammonia, methane, and air over a catalyst gauze; and the two ammonia dehydration routes, the methane – ammonia (BMA) and the Shawinigan processes, developed by Degussa and Gulf Oil Company, respectively. The latter are performed in externally heated ceramic tubes or in an electrically heated fluidized coke bed. Twenty-five percent of the hydrogen cyanide in the United States and 20 % in Western Europe is obtained as a byproduct in

the manufacture of acrylonitrile by the oxidation of propene in the presence of ammonia (Sohio technology).

1.2.1. *Andrussow Process*

The Andrussow process was developed around 1930 by L. ANDRUSSOW of I.G. Farben [45-47] and is the most widely used method for direct synthesis of hydrogen cyanide. The average capacity of single commercial installations is (5 – 30) × 10^3 t/a; large plants are operated by DuPont, Rohm and Haas, Novartis and Cyanco in the United States; ICI, Butachemie, Röhm and Elf-Atochem in Western Europe; and Mitsubishi Gas in Japan.

Figure 3 is a flow diagram of the Andrussow process. Natural gas, essentially sulfur-free methane, is mixed with ammonia. Compressed air is added in a volume ratio that corresponds closely to the theoretical reaction [48]:

$$CH_4 + NH_3 + 1.5\,O_2 \rightarrow HCN + 3\,H_2O \quad \Delta H = -474\ \mathrm{kJ/mol}$$

Figure 3. Simplified diagram of the Andrussow process

a) Reactor and ammonia scrubber; b) HCN absorption tower; c) HCN rectifier; d) Condenser

The mixture is passed over a platinum – rhodium or platinum – iridium gauze [49] catalyst; temperature and upper flammability limit should be monitored carefully [50], [51]. The reaction takes place at > 1000 °C, at around atmospheric pressure, and with a gas velocity through the catalyst zone of about 3 m/s. To avoid decomposition of HCN, the effluent gas from the reactor is quickly cooled in a waste-heat boiler, which produces the steam used in the process.

After the waste-heat boiler, the gas is washed with dilute sulfuric acid to remove unreacted ammonia; this is necessary to prevent polymerization of HCN. Because disposal of the resulting ammonium sulfate solution is expensive, other systems have been patented [52-54]. Alternatively, the off-gas from the reactor is passed through a monoammonium phosphate solution [55], [56], which converts the ammonia to diammonium phosphate. To effect thermal reversal of the phosphate equilibrium, the absorption solution is boiled in a stripper by injection of steam. The released ammonia is condensed and recycled to the reactor, while the regenerated monoammonium phosphate solution is pumped back to the absorber.

After the ammonia scrubber, the gas is passed through a countercurrent column in which the hydrogen cyanide is absorbed in cold water and the resulting solution is stabilized by adding acid (ca. 0.1 %). The hydrogen cyanide is stripped from the aqueous solution in a rectifier and condensed. The end product is highly pure and has a water content of less than 0.5 %. The aqueous absorber solution, containing traces of HCN, is cooled and fed back to the absorption tower. The residual gases, H_2, CO, and N_2, can be used for heating or methanated in a separate unit and recycled as feedstock for HCN manufacture [57].

The advantages of the Andrussow process include (1) long catalyst life, up to 10 000 h; (2) well-tested technology, with a simple and safe reaction system; and (3) high-purity HCN. A disadvantage is that the process is dependent on pure methane as a raw material to avoid carburization of the platinum catalyst; for example, a small percentage of higher hydrocarbon impurities rapidly causes problems with the catalyst system and reduces conversion rates. Other important poisons for platinum are sulfur and phosphorus compounds. A further problem is the relatively low yield based on methane (60 – 70 %) and ammonia (70 %), as well as the low hydrogen cyanide concentration in the product gas, so that recovery equipment must handle large volumes of gas.

The compositions of reaction and residual gases in the Andrussow and BMA processes are compared in Table 1.

Table 1. Composition of off-gases and residual gases (volume fractions, %) on the basis of pure methane and ammonia in the BMA and Andrussow processes

Compound	BMA		Andrussow *	
	After reaction	Residual	After reaction	Residual
HCN	22.9	$<10^{-2}$	7.6	$<10^{-2}$
NH_3	2.5	$<10^{-2}$	2.3	> 0
H_2	71.8	96.2	13.3	14.7
N_2	1.1	1.5	49.2	54.6
CH_4	1.7	2.3	0.3	0.4
CO			3.8	4.2
H_2O			23.1	25.7
CO_2			0.4	0.4

* Calculated because no consumption figures are available.

1.2.2. *Methane – Ammonia (BMA) Process*

The basis of the Degussa BMA process is the formation of hydrogen cyanide in the absence of oxygen [58-62]. The reaction

$$CH_4 + NH_3 \rightarrow HCN + 3\,H_2\,\Delta H = +252\,kJ/mol$$

is endothermic, requires temperatures above 1200 °C, and is performed in externally heated, alumina tube bundles, which are coated with a thin layer of a special platinum catalyst [63], [64]. Several of these bundles are fixed in a reaction furnace unit. A mixture of ammonia and methane (natural or refined gas with a content of 50 – 100 vol % methane) is passed through the tubes and quickly heated to 1300 °C at normal pressure. To avoid the formation of any disturbing deposits of carbon black, the NH_3/CH_4 ratio is kept between 1.01 and 1.08. After leaving the reaction tubes, the product gas is cooled to 300 °C by passage through a water-cooled aluminum chamber. A kinetic study has shown that a particular temperature profile is essential for this process [65].

The subsequent reaction steps, ammonia absorption and hydrogen cyanide isolation, are similar to those of the Andrussow process. A distinct advantage is the higher HCN content (Table 1) of the product gas, so that the number of steps and the size and cost of recovery equipment, are greatly reduced. The tail gas consists mainly of pure hydrogen. If this is not needed for other syntheses, it can be used as fuel for heating the furnace. About 80 – 87 % of the ammonia and 90 – 94 % of the methane are converted to hydrogen cyanide. The specific energy consumption of ca. 4×10^6 kJ/100 kg HCN reported thus far has been considerably decreased by more recent developments [66], [67]. A large part of the heating energy is recovered and used in the air preheater or steam generator.

If the methane supply is limited, the process can be carried out directly with liquefied hydrocarbons or ethanol, or in a three-step reaction starting from methanol [68-70]. Both Degussa and Lonza utilize the BMA route to produce hydrogen cyanide.

1.2.3. *Shawinigan Process*

In the Shawinigan process, hydrocarbon gases are reacted with ammonia in an electrically heated, fluidized bed of coke. The process, sometimes called the Fluohmic process, was developed in 1960 by Shawinigan Chemicals [71-74], now a division of Gulf Oil Canada.

In a circular reaction cavity constructed from alumina and silicon carbide, the mixture of ammonia and hydrocarbon (N/C ratio slightly > 1) passes through a fluidized bed of coke, heated by electrodes immersed in the bed. The chemical reaction is similar to the methane – ammonia process, but no catalyst is required and temperatures are kept above 1500 °C. Other carbon compounds, such as naphtha or lighter hydrocarbons, can also be converted. Propane is usually the main feedstock. The reaction can be described as

$$3\,NH_3 + C_3H_8 \rightarrow 3\,HCN + 7\,H_2\,\Delta H = +634\,kJ/mol$$

Unreacted feed gas is almost completely decomposed to the elements. This reduces the quantity of ammonia to be removed from the product gas and leads to the formation of coke particles. The control of coke particle size in the bed is an important operating parameter.

The reactor effluent contains up to 25 vol % HCN, 72 vol % H_2, 3 vol % N_2, and only 0.005 vol % NH_3. Coke is removed in a water-cooled, cyclone-entrained bed. The gas is further cooled and enters the absorption equipment where HCN is removed. The residual gas, nearly pure hydrogen, can be used for other chemical processes. Some of the hydrogen is recycled to the reaction unit to inhibit the formation of soot.

Coke from the cyclone is screened, and three fractions are separated, stored, and then fed back to the reactor system in the desired proportions to control the particle size distribution. By regulating the rate of coke recycling, the level of the fluidized bed and the reaction temperature can be controlled.

In practice, at least 85 % of the ammonia and up to 94 % of the hydrocarbon are converted to hydrogen cyanide. Because of the high electric power consumption (6.5 kWh per kilogram of HCN) the Shawinigan process would probably only be attractive where low-cost electricity is available.

This process is employed by Polifin in South Africa, by Arogenesas in Spain, and by Ticor in Australia.

1.3. Storage and Transportation [75], [76]

Handling, storage, and transportation of hydrogen cyanide are determined by its low boiling point, high toxicity, and instability in the presence of moisture, bases, or other impurities. The liquid acid is relatively uncorrosive. Materials compatible with HCN at normal temperatures are stainless steel, Hastelloy, and Monel. To prevent polymerization, stabilizing agents, such as sulfuric acid, phosphoric acid, oxalic or acetic acid, and sulfur dioxide are used. The type and quantity of stabilizer (usually < 0.5 %) depend on storage capacity, temperature, and residence time in a container. A combination of H_2SO_4 and SO_2 prevents the decomposition of HCN in the liquid and vapor phases. Larger quantities of hydrogen cyanide are stored at a maximum temperature of 5 °C and must be permanently recirculated.

Additionally, the color of the liquid is monitored and should not exceed APHA 20. To keep the concentration of gas below the danger level, good ventilation of buildings in which HCN is stored and handled is of primary importance. Hydrogen cyanide is usually classified by governmental authorities as very poisonous, requiring special packaging and transportation regulations. Similar strict procedures exist for solutions with an HCN content of 5 % or more. Smaller quantities of the stabilized acid are

transported in metal cylinders of up to 56 kg nominal water capacity in the United States and up to 60 kg in Germany. Cylinders cannot be charged with more than 0.55 – 0.60 kg of liquid HCN per 1 L bottle, and resistance to deformation must be tested up to 10 MPa before first filling. The water content should not exceed 3 %, and storage time should be less than one year. According to national regulations, transportation of quantities > 100 kg requires special permission. Procedures covering details of tank car size (up to 50 t), shipping, loading, and handling must be obeyed.

Hydrogen cyanide is mainly shipped by rail under the provisions of the applicable transport regulations. Transport in railcars is permitted only by approval of the competent authorities. The transport classifications of the most common transport regulations are as follows:

RID/ADR: Class 6.1, 1°; (a).

CFR 49: Class 6.1, UN 1051, PG I, “Poison Inhalation Hazard, Hazard Zone A”.

1.4. Economic Aspects and Uses

In 1998 the production capacity of synthetic hydrogen cyanide was about 650 × 10^3 t/a in the United States, 400 × 10^3 t/a in Europe, and 35 × 10^3 t/a in Japan. Without detailed knowledge of the type and age of catalyst used in various acrylonitrile plants, the additional amount of byproduct HCN can only be estimated. With an estimated HCN formation in the acrylonitrile processes of 10 %, an additional 180 × 10^3 t/a (United States), 130 × 10^3 t/a (Europe), and 60 × 10^3 t/a (Japan) is available. Currently, between 60 and 80 % of the existing production capacity is being utilized. The variety of uses has changed enormously in the past 15 years. Acrylonitrile production starting from acetylene was formerly the major consumer of hydrogen cyanide; in contrast, the Sohio process now in use yields HCN as a byproduct.

Today, the main outlet for HCN is the manufacture of methyl methacrylate. Acetone is treated with hydrogen cyanide to produce acetone cyanohydrin, which is treated with sulfuric acid and methanol to form methyl methacrylate. HCN is used to a similar extent in adiponitrile production, in which 2 mol HCN are added to 1 mol butadiene in a two-stage process. Virtually all the adiponitrile is then converted to hexamethylenediamine, a nylon precursor. Hydrogen cyanide reacts with chlorine to form cyanogen chloride (see Section Production) which is usually directly trimerized to cyanuric chloride. Herbicides based on cyanuric chloride have been successfully employed in recent years.

D,L-Methionine, one of the largest volume amino acids produced commercially, is manufactured in a complex, multistep synthesis which employs hydrogen cyanide as one of the raw materials. Other uses of HCN are in the production of chelating agents such as ethylenediaminetetraacetic acid (EDTA) or nitrilotriacetic acid (NTA), starting from aldehydes, amines, and hydrogen cyanide. A wide variety of organic intermediates can also be made from HCN and have considerable potential utility. The most important derivatives of hydrogen cyanide in inorganic chemistry are alkali metal cyanides and cyanide complexes of iron.

[Top of Page]

2. Metal Cyanides

Metal cyanides are compounds of metals in which one or more cyanide ions act as monodentate ligands with carbon as the preferred donor atom. Simple metal cyanides are represented by the formula M $(CN)_x$. Depending on the metal, simple cyanides dissolve more or less readily in water, forming metal ions and cyanide ions:

$$M(CN)_x \rightleftharpoons M^{x+} + xCN^-$$

The solubility is influenced by pH and temperature, especially because hydrogen cyanide is formed by the hydrolysis of cyanide:

$$CN^- + H_2O \rightleftharpoons HCN + OH^-$$

The cyanide complexes can generally be described by the formula A_y [M $(CN)_x$], where A is an alkali, alkaline earth, or heavy metal, and M is normally a transition metal. Most cyanide complexes in which A is an alkali or alkaline earth metal are highly soluble in water and form alkali or alkaline earth metal ions and complex transition metal cyanide anions, e.g.,

$$A_y[M(CN)_x] \rightleftharpoons yA^+ + [M(CN)_x]^{y-}$$

The complex cyanide anion may then undergo further dissociation and release cyanide ions:

$$[M(CN)_x]^{y-} \rightleftharpoons zCN^- + [M(CN)_{x-z}]^{(y-z)-}$$

The dissociation of the cyanide complex depends strongly on the type and valency of the complexed metal ion, as well as on the pH and concentration of the solution. Insoluble or slightly soluble cyanide complexes are formed when the alkali or alkaline earth metal anion A is replaced by a heavy metal ion. In this case, more complicated cyanide complexes are often formed, which cannot be described by the above-mentioned formula. Furthermore, most heavy metal ions allow the formation of mixed cyanide complexes in which one or more of the cyanide groups can be replaced by other ligands such as halides, pseudohalides, nitrogen oxides, sulfur compounds, water, or ammonia [4]. The properties and toxicities of these compounds depend on the structures of the metal cyanides.

2.1. Alkali Metal Cyanides

Since the introduction of the Castner process, sodium cyanide [143-33-9] has been the metal cyanide with the greatest commercial importance. Until about 1900, potassium cyanide [151-50-8] was the more common compound, because it could

be produced more easily by melting potassium carbonate with potassium hexacyanoferrate(II), one of the oldest known cyano compounds. The properties and reactions of both alkali cyanides are very similar.

2.1.1. *Properties*

Sodium and potassium cyanide are colorless, hygroscopic salts with a slight odor of hydrogen cyanide and ammonia in moist air. They are fairly soluble in water (Fig. 4), and the sodium salt forms two hydrates: NaCN · 2 H_2O below 35 °C and NaCN · 1/2 H_2O at higher temperatures. Further physical properties are listed in Table 2. In the absence of air, carbon dioxide, and moisture, the alkali metal cyanides are stable, even at fairly high temperature, and can be stored indefinitely [2].

Table 2. Physical properties of NaCN [143-33-9] and KCN [151-50-8]

Physical quantity	NaCN	KCN
M_r	49.015	65.119
mp	561.7 °C (98 wt %)	634.5 °C
bp	1500 ± 10 °C	
ϱ, density	1.620 g/cm^3 (6 °C, rhombic)	1.553 g/cm^3 (20 °C, cubic)
	1.595 g/cm^3 (20 °C, cubic)	1.56 g/cm^3 (25 °C, cubic)
	1.19 g/cm^3 (850 °C, fused)	
c_p, specific heat capacity	1.667 kJ kg^{-1} K^{-1} (273.1 K)	1.00 kJ kg^{-1} K^{-1} (25 – 72 °C)
	17.950 kJ kg^{-1} K^{-1} (288.0 K)	
	1.402 kJ kg^{-1} K^{-1} (298.6 K)	
H, enthalpy (25 °C)	–89.9 kJ/mol	–112.63 kJ/mol
ΔH_f, heat of fusion	314 kJ/kg	225 kJ/kg
ΔH_v, heat of vaporization	3185 kJ/kg	
p_v, vapor pressure	0.10 kPa (800 °C)	
	1.65 kPa (1000 °C)	
	11.98 kPa (1200 °C)	
	39.10 kPa (1350 °C)	
Solubility in 100 g of		
Water	see Figure 4	see Figure 4
Ethanol, 100 %	1.235 g (25 °C)	0.57 g (19.5 °C)
Ethanol, 95 %	2.445 g (25 °C)	
Methanol	6.44 g (15 °C)	4.91 g (19.5 °C)
	4.58 g (25 °C)	
	4.10 g (67.4 °C)	
NH_3, liquid	58 g (–31 °C)	4.55 g (–33.9 °C)

Figure 4. Solubility of NaCN and KCN in water

* Solid phase: ice–NaCN · 2 H_2O or ice–NaCN

** Solid phase: ice–KCN

Dry CO_2 does not react with dry alkali metal cyanides; however, in moist air slow decomposition takes place, even at normal temperature, releasing HCN:

$$2\,NaCN + CO_2 + H_2O \rightarrow Na_2CO_3 + 2\,HCN$$

When this occurs, the salt sometimes becomes brownish because of the formation of polymerization products of HCN (azulmic acid). Alkali metal cyanides are totally decomposed to HCN by the action of strong acids, e.g.,

$$2\,NaCN + H_2SO_4 \rightarrow 2\,HCN + Na_2SO_4$$

At elevated temperatures, oxygen reacts with alkali metal cyanides, to form the metal cyanate and carbonate, nitrogen, and

carbon dioxide [79]:

$$2\,NaCN + O_2 \rightarrow 2\,NaOCN$$

$$2\,NaOCN + 3/2O_2 \rightarrow Na_2CO_3 + N_2 + CO_2$$

The oxidation of alkali metal cyanides to cyanates by bubbling an air stream through an alkaline melt is used for the bath nitriding of steel [80], [81]. Oxides of lead, tin, copper, nickel, and iron react with alkali metal cyanides above 560 °C to form the corresponding cyanate and carbonate, nitrogen, carbon dioxide, and the corresponding metal [82], [83]. Violent oxidation of alkali metal cyanides can result from the addition of strong oxidants such as nitrate, nitrite, or chlorate to a melt:

$$NO_3^- + CN^- \rightarrow N_2 + CO_3^{2-}$$

$$5\,NO_2^- + 3\,CN^- \rightarrow 4\,N_2 + O^{2-} + 3\,CO_3^{2-}$$

These reactions have been utilized for the destruction of waste salts from hardening shops [84], [85].

When alkali metal cyanides are dissolved in water, a pH-dependent, reversible equilibrium is established between hydrocyanic acid and alkali-metal hydroxide [86], [87]:

$$NaCN + H_2O \rightleftharpoons HCN + NaOH$$

For example, in an aqueous solution of NaCN at pH 9.4, half of the total cyanide is present as HCN [88] (cf. Fig. 1). As a result of this hydrolysis, solutions of alkali-metal cyanides in water are always strongly alkaline. Furthermore, commercial products always contain small amounts of alkali metal hydroxide to enhance stability; hence, the actual pH values of solutions are usually higher than those calculated on the basis of the cyanide concentration and the hydrolysis reaction (Table 3).

Table 3. pH values of aqueous solutions with varying concentrations of NaCN and KCN [72]

	Concentration, mol/L					
	1	10^{-1}	10^{-2}	10^{-3}	10^{-4}	10^{-5}
NaCN	11.64	11.15	10.67	10.15	9.6	8.9
KCN		11.37	10.91	10.35		

Nevertheless, when alkali metal cyanides are dissolved in tap water, discoloration and precipitation of brownish-black amorphous polymerization products of HCN (azulmic acid) may occur when the water contains too much CO_2 or other acidic components. When solutions of alkali-metal cyanides are stored for a long time or heated, slow hydrolysis of the C≡N bond takes place to yield the alkali metal formate and ammonia [89], [90]:

$$NaCN + 2\,H_2O \rightarrow HCOONa + NH_3$$

The hydrolytic decomposition of concentrated NaCN solutions can be suppressed, even at 60 – 80 °C, by the addition of 0.5 – 2 % NaOH [91]. However, the hydrolysis is fast and complete when the reaction is carried out at 170 °C under pressure [92], [93]. This process has been investigated for the destruction of cyanide wastes from metal hardening plants [94]. Atmospheric oxygen achieves only partial oxidation of cyanide in aqueous solution at elevated temperature [95]; however, the reaction can be enhanced by the use of catalysts such as activated carbon [96], [97]. A fast conversion of cyanide to cyanate is brought about by ozone at pH 10 – 12; this is followed by a slower oxidation to nitrogen and carbonate [98], [99].

Cyanide is also oxidized to cyanate by hydrogen peroxide [100] and by peroxomonosulfate, peroxodisulfate [101], and permanganate ions [102]. The anodic oxidation of cyanide leads, via cyanogen and the cyanate, to the carbonate, nitrogen, ammonia, and urea [103]. Halogens react with cyanide in aqueous solution to give cyanogen halides, XCN (X = Cl, Br, I), which are hydrolyzed more or less quickly, depending on the pH and temperature of the solution [104] (see Section Properties).

Reaction with chlorine or hypochlorite above pH 11.5 is the most widely used process for detoxification of solutions and wastewaters containing cyanide at concentrations below 1 g/L.

The reaction of alkali cyanides with sulfur or polysulfides in aqueous solution at elevated temperature is used for the production of alkali metal thiocyanates [105]. The reaction with thiosulfate to give thiocyanate is used therapeutically in the treatment of cyanide poisoning [106]. Heavy metal ions react in aqueous solution with cyanide to yield insoluble cyanides, all of which dissolve in the presence of excess cyanide to give stable complex salts [107]. These compounds play an important role in metallurgy and electroplating [108]. Some base metals (e.g., zinc or nickel) and, in the presence of oxygen or oxidizing agents, even precious metals (e.g., gold or silver) are dissolved by aqueous solutions of alkali metal cyanides [109]. This property of alkali metal cyanides has been utilized for about 100 years in the leaching of precious metals ores:

$$4\,NaCN + 2\,Au + 1/2\,O_2 + H_2O \rightarrow 2\,Na[Au(CN)_2] + 2\,NaOH$$

Tantalum, titanium, and tungsten are not attacked by alkali metal cyanide solutions at room temperature.

Alkali metal cyanides react with carbonyl groups of organic compounds in aqueous solution to form cyanohydrins [111], [112]:

Organic compounds with labile halogen atoms can be converted by reaction with alkali metal cyanides in aqueous solution to nitriles, which can be further processed to give carboxylic acids, amines, etc.:

$$RCl + NaCN \rightarrow RCN + NaCl$$

2.1.2. *Production*

The large-scale production of alkali metal cyanides began in the second half of the 19th century, when J. S. MAC ARTHUR and the FORREST Brothers patented their process for the extraction of gold and silver from ores. The manufacturing method was based on work of F. and E. RODGERS [113], who fused potassium or sodium carbonate with potassium hexacyanoferrate (II), for which animal blood and waste were used as raw materials. A large number of modified processes were patented up to 1900, but the production of cyanides on a major industrial scale finally began with the development of a process based on a patent of H. J. CASTNER, which employed the reaction of sodium metal with charcoal and ammonia [114]:

$$Na + C + NH_3 \rightarrow NaCN + 3/2\,H_2$$

The Castner process was originally a two-stage process, which was developed mainly at Degussa [115], [116] and used there until 1971. In the 1960s sodium cyanide and potassium cyanide are produced exclusively by the neutralization process, which is based on the stoichiometric reaction of a solution of sodium or potassium hydroxide with liquid or gaseous hydrogen cyanide [117-121].

$$MOH + HCN \rightarrow MCN + H_2O$$

Although the process appears very simple, it involves a number of technical difficulties, which result from the tendency of hydrogen cyanide to polymerize, as well as from the hydrolysis of the alkali metal cyanides and their reactivity with carbon dioxide and air. High-grade products can be obtained only when the production process is controlled very closely. In principle, all plants employ the following process steps, which differ only in some details.

Gaseous or liquid HCN is first introduced continuously into concentrated solutions of NaOH or KOH at elevated temperature. The heat of neutralization is used for the subsequent vaporization of water. The use of special mixing devices and the addition of 0.2 – 3 % excess NaOH prevents polymerization [122-124]. Simultaneously or in a second step, water is vaporized under reduced pressure and the alkali metal cyanide is precipitated below 100 °C. The shorter the residence time of the cyanide in solution, the cleaner the product and the lower the content of hydrolysis products and iron impurities [125], [126].

The cyanide crystals are separated by filtration or centrifugation, and various methods are used to dry the wet salt, which still contains about 12 % water. A two-step drying process with hot, CO_2-free air at 200 – 430 °C is advantageous because the product remains free flowing [127], [128]. Sometimes fluidized-bed dryers are utilized [129]. In any case, the used air must be washed and the wastewater detoxified to avoid pollution problems. Standard equipment can be employed for further processing of the salt, which still contains up to 1 % moisture at this stage [130]. The final commercial forms are powder, granulate, briquettes, or tablets [131], [132].

The production of NaCN from nitrogenous waste from the manufacture of sugar [133] is the precursor of the “neutralization process.” This process no longer has any commercial importance.

2.1.3. *Commercial Forms, Specifications, and Packaging*

Most alkali metal cyanides are supplied in solid form. Common commercial forms for NaCN and KCN are granular products composed of irregularly shaped particles ca. 0.1 – 5 mm in size, nearly free of dust; molded briquettes weighing 15 – 40 g; and cylindrical tablets ca. 25 – 40 mm in diameter and weighing 20 – 40 g.

Briquettes and tablets are the preferred product forms, especially for gold extraction by cyanidation because of their dust-free nature. Smaller amounts of NaCN and KCN are used as granules or as coarse-grained powders for the preparation of mixtures or for direct application in the electroplating industry or in organic synthesis.

The specifications according to the German standards [134] for the electroplating industry (DIN 50 971) for NaCN and KCN are listed in Table 4. The quality of commercial products normally exceeds the requirements of DIN 50 971.

Table 4. Specifications and average analysis of NaCN and KCN (data given in wt % or ppm = mg/kg; M = Na or K)

	NaCN		KCN	
	DIN 50 971	Average analysis	DIN 50 971	Average analysis
MCN, %	> 98.0		98 – 99	

CN^-, %	51.5	> 52.0	39.0	> 39.0
MOH, %		≈ 0.5		≈ 0.1
M_2CO_3, %		≈ 0.5		≈ 1.0
Cl^-, %		≈ 0.02		≈ 0.0015
SO_4^{2-}, %		≈ 0.05		< 0.01
SO_3^{2-}, %		< 0.05		< 0.01
S^{2-}, ppm		< 1		< 1
MOCN, %		≈ 0.1		≈ 0.1
SCN^-, %		< 0.01		< 0.01
HCOOM, %		≈ 0.5		≈ 0.3
H_2O, %		≈ 0.2		≈ 0.2
Sb, ppm	< 5	< 5	< 5	< 5
As, ppm	< 5	< 5	< 5	< 5
Pb, ppm	< 50	< 50	< 50	< 50
Cd, ppm	< 10	< 10	< 10	< 10
Fe, ppm	< 50	< 50	< 50	< 50
Cu, ppm	< 10	< 10	< 10	< 10
Ni, ppm	< 50	< 50	< 50	< 50
Zn, ppm	< 20	< 20	< 20	< 20
Sn, ppm	< 80	< 80	< 30	< 30
Na, %		< 48	< 0.5	< 0.3
Insolubles, %	< 0.005	< 0.001	< 0.005	< 0.001

Today, the preferred packaging forms for NaCN and KCN are flexible intermediate bulk containers (FIBCs) in a plywood box, especially for the mining industry. For further protection and to make the packaging air- and watertight, an additional polyethylene inliner is used inside the plywood box. This type of package usually contains 1 t. If the customer is located in the vicinity of a production plant, large quantities of cyanide can also be supplied in returnable metal IBCs (Intermediate Bulk Container), generally containing 1 t of product.

For smaller customers, for example, the electroplating industry, solid alkali metal cyanides are also supplied in plated steel drums containing 50 or 100 kg of cyanide. The lid of the drum is fixed with a locking ring and hermetically sealed.

All types of packaging must meet the official requirements for the transportation of toxic substances (UN approval). Furthermore, the packagings must be labeled according to the transport regulations including the proper shipping name, the UN product number, labeling as a toxic product (skull and crossbones, marine pollutant labels) and the country of origin, as well as recommendations on safe handling and first aid procedures.

Sodium and potassium cyanides can be supplied as stable aqueous solutions [91] with about 30 wt % NaCN or 40 wt % KCN in containers with a capacity of at least 20 m^3, in railcars or tank trucks. However, liquid cyanide supply is only economically feasible within a limited radius of the production plant and is not permitted by sea freight. The concentration of the solution can be adjusted to ensure that, even in winter, no precipitation occurs. Liquid cyanide is easier to handle and is the preferred form when large quantities of cyanides are required and aqueous solutions can be used. Major consumers are the mining industry and the organic chemical industry.

2.1.4. *Transportation, Storage, and Handling*

Transportation. Alkali metal cyanides can be shipped by road, rail, or sea freight under the provisions of the applicable transport regulations. The transport classifications of the most common transport regulations are as follows:

Alkali metal cyanide solid: RID/ADR (European land transport) and ADNR (European inland navigation): Class 6.1, 41° a)

IMDG Code (marine transport) and CFR 49 (U.S. domestic transport): Class 6.1, UN 1689 (for NaCN), UN 1680 (for KCN), PG I

Alkali metal cyanide solutions: RID/ADR (European landtransport) and ADNR (European inland navigation): Class 6.1, 41° a), b), or c) (depending on the concentration)

IDMG Code (marine transport) and CFR 49 (U.S. domestic transport): Class 6.1, UN 1935, PG I, II, or III (depending on the concentration)

They must never be stored or transported in the same transport unit together with acids or acid salts, foods, feedstuffs, or anything else intended for human or animal consumption.

Carriers should be selected on the basis of their safety commitment and record as well as commercial factors. The Safety and Quality Assessment System (CEFIC or CMA) is an objective means of carrying out this selection for road transportation.

Hauliers should be experienced in handling cyanides and know how to act in case of emergencies.

As well as the general provisions of ADR, driver training should include awareness of the specific hazards of cyanides.

Appropriate personal protective equipment must be carried.

Loads containing cyanides must only be left unattended in secure areas away from the general public. The vehicle shall be locked.

All incidents and accidents must be reported, investigated, and corrective action taken to prevent recurrence.

When severe weather conditions are experienced during transport, for example, icy roads, snow, or poor visibility caused by fog, the delivery should be stopped at the next suitable parking place. Delivery should not resume until weather conditions improve.

All delays during transport caused be severe weather conditions, breakdowns, or other reasons must be reported to the consignor immediately.

Transport accidents must also be reported to the consignor immediately. An on-board telephone is highly recommended.

If emergency action must be taken by drivers when leaks, spills, or fire occur during transport, the instructions given in Transport Emergency Card must be followed.

Drums, boxes, or intermediate bulk containers must be properly secured to minimize the risk of movement during transit or loss of containment in an incident.

For transportation by truck or rail the use of tilts is recommended as the solid sides minimize lateral movement during transit. Where possible, material should be palletized and the pallet securely fixed to the vehicle.

Free space in all means of transport should be minimized. This can be achieved by efficient packing and/or use of appropriate void fillers. Particular attention should be paid to securing the load adjacent to the container doors to minimize the risk of drums falling out when the doors are opened.

Small loads of a few drums, often as part of a mixed load, must be segregated from noncompatible cargo and securely fixed. A storage box fixed to the vehicle which provides secondary containment in the event of spillage is suitable.

Sodium cyanide solution should only be transported on defined routes. The route to be followed must be selected carefully and should be known to both the haulier and the consignor or supplier. As far as possible, the route should utilise motorways/highways and avoid major population centers.

Storage and Handling. Any type of packaging that contains cyanide must be stored in a dry place and protected against corrosion. Rooms in which cyanides are stored and processed must be well ventilated. A full mask with a type B filter (identifying color gray, shelf life unused max. five years), must be worn when HCN might be present. The cyanide storage area must be clearly marked and unauthorised persons must never be allowed access to rooms in which cyanides are stored or processed. Therefore, a cyanide area must be separated from other areas, e.g., by fences or walls. In case of an emergency, powder fire extinguishers, safety showers, eye washes, and antidotes should be available in the immediate vicinity.

If the original cyanide drums are used as storage containers, they must be tightly closed immediately after removal of cyanide and should not be allowed to stand open. Stainless steel should be used as construction material for equipment that comes in contact with cyanide solutions up to 100 t [109]. However, concentrated cyanide solutions must be stored in steel or stainless steel containers which are protected against leakage by a collecting basin constructed of alkali-resistant concrete.

Spilled solid cyanide must be swept up immediately with a dustpan and brush and returned to the container. If it has become dirty and unusable, the cyanide must be destroyed or disposed of in accordance with legal regulations. In addition, spilled cyanide solutions and wastewater that contains cyanide must be detoxified (see Section Wastewater Treatment) before discharge into public sewage system or open water. Containers, equipment, and any objects or floor areas that have become contaminated with cyanide must be washed thoroughly with water, which must then also be detoxified.

Work with cyanide requires the greatest possible caution and strictest adherence to all safety regulations. Never work alone when handling cyanide, do not eat, drink, smoke, use snuff, or chew gum or tobacco. Also do not store any food, beverages, or smoking material in the cyanide area. Prevent any contact of cyanide with the skin or eyes, as well as the respiration of cyanide dust or hydrogen cyanide gas. If a danger of cyanide contamination exists, rubber gloves, rubber boots, a rubber apron, and safety goggles or protection for the face and head must be worn. Safety showers and eye washes should be located in the immediate vincinity of each cyanide area. Prevent the development of cyanide dust. If cyanide dust is produced, wear approved respiration protection, preferably a full-face mask. Filters must be replaced after each use. Never bring acids, acid salts, or oxidants into contact with cyanide or allow combined storage, because any direct contact would generate highly poisonous gaseous hydrogen cyanide. Never handle cyanide at a pH which may produce hydrogen cyanide gas.

After handling cyanide, wash any contaminated parts of the body, especially the hands thoroughly with copious water. Contaminated clothes should be washed at work and never at home.

Further safety information is compiled in the Chemical Safety Data Sheets of the Manufacturers Association of the Chemical

Industry [135], [136].

2.1.5. *Economic Aspects and Uses*

In gold extraction by cyanidation the countercation has no effect on the leaching process. Therefore, the cheaper cyanides are used for this application. As potassium cyanide is more expensive than sodium cyanide, the latter is used exclusively in this industry. In other applications, the countercation is of importance, and potassium cyanide has some advantages, e.g., in electroplating, because the potassium ion has greater mobility than the sodium ion.

Gold and Silver Leaching. The leaching of precious metals such as gold and silver from ores is the main application of NaCN. As a result of its unique chemical affinity, especially for gold, cyanide forms the most stable complex of all lixiviants available, which is important for the complete recovery of the accessible gold in the ore. The high affinity for gold also enables operation at relatively low cyanide concentration to nevertheless achieve a high recovery.

As cyanidation has been known and applied for more than 100 years in all five continents, the potential effect of cyanide on the environment has been studied in detail, and suitable technology for effective cyanide detoxification is available and can be used to avoid environmental impact of cyanide.

All efforts to replace cyanide with other less toxic complexing agents have remained unsuccessful. All other lixiviants, such as the systems chloride/chlorine, bromide/bromine, hydrogen sulfide, and thiourea, require much higher concentrations, more complicated processes, and higher costs compared to cyanidation technology. Furthermore, these reagents are also toxic, and their impact on the environment as well as suitable detoxification techniques have not yet been studied in detail.

Therefore, cyanide will remain the technology of choice in the future for gold extraction, especially because developments in cyanide recovery and cyanide detoxification of the tailings are constantly improving the environmental suitability of the cyanidation process.

Base Metal Flotation. Cyanide is used as a depressant in the selective flotation of zinc, lead, copper, and iron [138]. This application is, however, declining because other, higher performance and more economical compounds have become increasingly popular over the last few years.

Electroplating (⟶ Electrochemical and Chemical Deposition – Specific Deposits and Plating Solutions***).*** Large quantities of alkali metal cyanides, as well as the complex cyanides of copper, zinc, and cadmium manufactured therefrom, are used in electroplating processes. In particular, the plating of iron, steel, and zinc is carried out with cyanide-containing electrolytes. Very good corrosion protection resulting from the even deposition of layers, ease of use, and low sensitivity of the bath to impurities are the main advantages of these electrolytes. In this application, potassium cyanide is preferred, patricularly for the deposition of gold and silver. Generally, electrolytes based on potassium salts have the advantages of better performance and lower sensitivity to impurities [139].

When the highest quality is required, cyanide pretreatment and degreasing baths are still in use today, especially since attempts to employ other strong complexing agents have failed because of insurmountable wastewater problems.

Metal-Surface Hardening in Molten Salts. Sodium and potassium cyanides are important because they release nitrogen or carbon or both onto the surface of the material being treated at relatively low temperatures. The Tufftride process is employed primarily for the hardening of steel parts used as tools or in engines where they are highly stressed [140-143]. Particularly sodium cyanide is used in this application, because of its lower price.

Organic Synthesis [111]. Large quantities of sodium cyanide are used to introduce cyano groups into organic compounds. This is the first step in the synthesis of a variety of well-known compounds used in pharmacy, complex chemistry, and polymer chemistry.

In particular, organic halogen compounds react with sodium cyanide in water or polar aprotic solvents to form nitriles:

$$\mathrm{NaCN + RCl \rightarrow RCN + NaCl}$$

The nitriles can be converted to carboxylic acids, amides, esters, and amines. The sodium salt of cyanoacetic acid, for example, is manufactured in this way and is raw material for the manufacture of malonic acid, caffeine, and numerous other important organic products.

Inorganic Chemistry. An important application of sodium and potassium cyanides is the production of heavy metal cyanides, particularly complex iron cyanides (see Section Heavy-Metal Cyanides).

2.2. Alkaline Earth Metal Cyanides

Properties and Uses. The properties of the alkaline earth metal cyanides differ from those of the alkali metal cyanides. They are less stable and decompose at elevated temperatures to release HCN. Even when alkaline earth metal cyanides are in contact with moist air or dissolved in water, hydrolysis takes place, e.g.,

$$\mathrm{Ca(CN)_2 + 2\,H_2O \rightarrow Ca(OH)_2 + 2\,HCN}$$

As a consequence, pure solid calcium cyanide is unstable, and the commercial product can only be manufactured in amorphous form with a content of about 45 – 50 % NaCN equivalent, known as black cyanide. As a solution, calcium cyanide is only sufficiently stable for commercial use at concentrations below 17 %.

Liquid and solid calcium cyanide are only produced in South Africa, where they are used for the leaching of precious metals from ores [145].

Apart from this compound, only barium cyanide has any commercial importance as a result of its use in electroplating to separate carbonate from cyanides containing electrolytes [139]. Some of the physical properties of these compounds are listed in Table 5.

Table 5. Physical properties of the alkaline-earth-metal cyanides

Property	$Mg(CN)_2$ [4100-56-5]	$Ca(CN)_2$ [592-01-8]	$Sr(CN)_2$ [52870-08-3]	$Ba(CN)_2$ [542-62-1]
M_r	76.37	92.12	139.67	189.40
mp, °C		> 350		≈ 600
Decomp., °C	> 300	≈ 640	> 500	> 600
Other crystal forms	$Mg(CN)_2 \cdot 2 NH_3$	$Ca(CN)_2 \cdot 2 NH_3$	$Sr(CN)_2 \cdot 4 H_2O$	$Ba(CN)_2 \cdot 2 H_2O$

Production. The alkaline earth metal cyanides can be obtained by reaction of the corresponding metal hydroxides with hydrogen cyanide [5]. However, only liquid calcium cyanide is produced by this method. The resulting product has a brownish color due to polymerization of HCN, liberated by hydrolysis.

The production process of the commercially available solid calcium cyanide is different. Black cyanide is produced by treating calcium carbide with nitrogen gas to give calcium cyanamide. The crude cyanamide is then mixed with sodium chloride and heated in electric furnaces above 1000 °C [146]. The cyanamide is converted into calcium cyanide, which is quenched to produce amorphous flakes. The reaction product is gray-black because of the presence of 1 – 2 % carbon. The cyanide content of the amorphous black cyanide is ca. 45 – 50 % NaCN equivalent. Other constituents are 32 % NaCN, 12 % CaO, 2 – 3 % $CaCl_2$, and 2 – 3 % CaNCN.

2.3. Heavy-Metal Cyanides

Heavy metals usually form stable, insoluble or sparingly soluble simple cyanides $M(CN)_x$, which dissolve in the presence of excess alkali metal cyanide to form stable complex salts [107]:

$$M(CN)_x + yCN^- \rightleftharpoons \left[M(CN)_{x+y}\right]^{y-}$$

where $x = 1 – 3$; $y = 1 – 4$

When dissolved in water, the complex cyanide anions tend to dissociate, and various dissociation equilibria are established. The dissociation properties of the most important heavy-metal cyanides are shown in Table 6.

Table 6. Stability of heavy-metal cyanide complexes [4], [107]

Dissociation equilibria	$pK_{dissociation}$
$[Pb(CN)_4]^{2-} \rightleftharpoons Pb^{2+} + 4 CN^-$	10.3
$[Cd(CN)_4]^{2-} \rightleftharpoons [Cd(CN)_3]^- + CN^-$	2.5
$[Cd(CN)_3]^- \rightleftharpoons Cd^{2+} + 3 CN^-$	14.7
Σ	17.2
$[Zn(CN)_4]^{2-} \rightleftharpoons [Zn(CN)_3]^- + CN^-$	1
$[Zn(CN)_3]^- \rightleftharpoons Zn^{2+} + 3 CN^-$	17.9
Σ	18.9
$[Ag(CN)_2]^- \rightleftharpoons Ag^+ + 2 CN^-$	20.9
$[Ni(CN)_4]^{2-} \rightleftharpoons Ni^{2+} + 4 CN^-$	≈ 22
$[Cu(CN)_4]^{3-} \rightleftharpoons [Cu(CN)_3]^{2-} + CN^-$	1.5
$[Cu(CN)_3]^{2-} \rightleftharpoons [Cu(CN)_2]^- + CN^-$	5.3
$[Cu(CN)_2]^- \rightleftharpoons Cu^+ + 2 CN^-$	23.9

	Σ	30.7
$[Fe(CN)_6]^{3-} \rightleftarrows Fe^{3+} + 6\ CN^-$	≈	36

$[Hg(CN)_4]^{2-} \rightleftarrows Hg^{2+} + 4\ CN^-$		40.5
$[Fe(CN)_6]^{4-} \rightleftarrows Fe^{2+} + 6\ CN^-$	≈	42
$[Co(CN)_6]^{4-} \rightleftarrows Co^{2+} + 6\ CN^-$	≈	64
$[Pt(CN)_4]^{2-} \rightleftarrows Pt^{2+} + 4\ CN^-$	≈	40
$[Pd(CN)_4]^{2-} \rightleftarrows Pd^{2+} + 4\ CN^-$	≈	42

2.3.1. *Iron Cyanides*

2.3.1.1. *Properties*

The most important iron cyanides are the hexacyanoferrate(II), ferrocyanide, $[Fe(CN)_6]^{4-}$, and the hexacyanoferrate(III), ferricyanide, $[Fe(CN)_6]^{3-}$, complexes, which have an octahedral configuration. They are among the most stable inorganic complexes and are practically nontoxic because of the strong bonding between iron and cyanide (for LD_{50} values, see Toxicology and Occupational Health). Practically none of the known cyanide reactions can be observed when these compounds are dissolved in water. Only when irradiated with UV light does the hexacyanoferrate(II) ion decompose slowly at normal temperature to form cyanide ions [148]:

$$[Fe(CN)_6]^{4-} + H_2O \underset{\text{dark}}{\overset{\text{UV}}{\rightleftharpoons}} [Fe(CN)_5H_2O]^{3-} + CN^-$$

In the absence of UV light, only very strong oxidants like ozone are able to oxidize the cyanide and destroy the hexacyanoferrate(II) complex slowly at elevated temperature [149]:

$$2[Fe(CN)_6]^{4-} + 13\,O_3 + 4\,OH^- + H_2O \rightarrow 2\,Fe(OH)_3 + 12\,OCN^- + 13\,O_2$$

Permanganate, peroxodisulfate, hypochlorite, chlorine, iodine, cesium(IV), and other oxidants oxidize hexacyanoferrate(II) to hexacyanoferrate(III) at moderate temperatures [150], e.g.,

$$5\,[Fe(CN)_6]^{4-} + MnO_4^- + 8\,H^+ \rightarrow 5[Fe(CN)_6]^{3-} + Mn^{2+} + 4\,H_2O$$

This reaction is used for the determination of hexacyanoferrate (II) in water. Hydrogen peroxide oxidizes hexacyanoferrate(II) to hexacyanoferrate(III) below pH 3 and reduces hexacyanoferrate(III) to hexacyanoferrate(II) above pH 7:

$$2[Fe(CN)_6]^{4-} + H_2O_2 + 2\,H^+ \rightarrow 2[Fe(CN)_6]^{3-} + 2\,H_2O$$

$$2[Fe(CN)_6]^{3-} + H_2O_2 \rightarrow 2[Fe(CN)_6]^{4-} + 2\,H^+ + O_2$$

When acidified with mineral acids, solutions of hexacyanoferrates decompose slowly at room temperature and more rapidly when heated, releasing HCN and forming precipitates of iron(II) hexacyanoferrate(II) [14460-02-7] [150]:

$$3[Fe(CN)_6]^{4-} + 12\,H^+ \rightarrow 3\,H_4[Fe(CN)_6] \rightarrow 12\,HCN + Fe_2[Fe(CN)_6]$$

Insoluble or sparingly soluble metal hexacyanoferrates(II) are formed by the addition of aqueous solutions to neutral or weakly acidic solutions of metal salts, particularly heavy metal salts [150]:

$$4\,M^+ + [Fe(CN)_6]^{4-} \rightarrow M_4[Fe(CN)_6]\,(\text{sparingly soluble})$$

$$2\,M^{2+} + [Fe(CN)_6]^{4-} \rightarrow M_2[Fe(CN)_6]\,(\text{sparingly soluble})$$

These reactions are used to separate heavy metals from solutions for the purpose of refining and for the production of colored pigments, e.g., Prussian blue pigments, which contain the hexacyanoferrate(III) anion:

$$M^+ + Fe^{2+} + [Fe(CN)_6]^{3-} \rightarrow MFe[Fe(CN)_6]$$

M = K, Na, NH_4, Cu

Multinuclear complexes are formed by the thermolysis of hexacyanoferrate(II) complexes with complex cations [5]. Many anionic and neutral ligands can be introduced into the hexacyanoferrate anion by substitution of one CN group, to form pentacyano complexes [4], [5].

$$[Fe(CN)_6]^{3-/4-} + X \rightarrow [Fe(CN)_5X]^{2-/3-} + CN^-$$

where X = H_2O, NH_3, NO, NO_2, NO_5, CO

$$[Fe(CN)_6]^{3-/4-} + X^- \rightarrow [Fe(CN)_5X]^{3-/4-} + CN^-$$

where X = SCN, NCS.

Some of these compounds are used in analytical chemistry. Hexacyanoferrate(II) reacts with a variety of organic amino compounds to form insoluble or slightly soluble salts of general composition BA, B_3A_2, B_2A, B_3A, and B_4A, where B is the cationic nitrogen compound and A the anionic hexacyanoferrate(II) [4]. These reactions are used in analytical and pharmaceutical chemistry. Hexacyanoferrate(III) is a strong oxidant which can dissolve metals; it is used in photographic processes [151] and etching techniques [152]:

$$[Fe(CN)_6]^{3-} + M \rightarrow [Fe(CN)_6]^{4-} + M^+$$

The hexacyanoferrates(II) of sodium, potassium, and calcium crystallize with different amounts of water of crystallization, whereas potassium hexacyanoferrate(III) is obtained in anhydrous form. The hexacyanoferrates(II) start to lose water of crystallization above 30 °C and become anhydrous white powders above 80 °C. All hexacyanoferrates decompose above 400 °C to form alkali metal or calcium cyanide, elemental iron, carbon, and nitrogen, e.g.,

$$Na_4[Fe(CN)_6] \rightarrow 4\,NaCN + Fe + 2\,C + N_2$$

The alkali metal hexacyanoferrates are readily soluble in water; the solubility of the calcium salt is more than twice that of the sodium salt (Table 7). Double salts of low solubility may be formed in the presence of Ca^{2+} and K^+ or NH_4^+ ions.

Table 7. Solubilities of hexacyanoferrates in water (wt % of anhydrous salt)

Compound	Temperature, °C		
	20	50	80
$Na_4[Fe(CN)_6]$	16	26	38
$K_4[Fe(CN)_6]$	22	32	40
$Ca_2[Fe(CN)_6]$	36	42	44
$K_3[Fe(CN)_6]$	31	39	45

2.3.1.2. *Production*

Historically, the preparation of hexacyanoferrates(II) was based on the fusion of potash with iron compounds and animal residues such as hide, horns, or dried blood, which led to the German name *gelbes Blutlaugensalz* (yellow salt of blood lye). Later, the absorption of hydrogen cyanide from coal gas on iron hydroxide was used to produce hexacyanoferrates. Today, synthetic hydrogen cyanide, iron(II) chloride, and alkali metal or calcium hydroxide are the raw materials for the large-scale production of hexacyanoferrates(II) on a large scale.

Calcium hexacyanoferrate(II) is usually the primary product, which is subsequently converted to the potassium and sodium salts. Liquid hydrogen cyanide and an aqueous solution of iron(II) chloride are mixed with calcium hydroxide solution in stoichiometric amounts in a stirred reactor:

$$3\,Ca(OH)_2 + FeCl_2 + 6\,HCN \rightarrow Ca_2[Fe(CN)_6] + CaCl_2 + 6\,H_2O$$

After filtration, the solution is concentrated by evaporation of water under reduced pressure, and the calcium hexacyanoferrate(II) crystallizes with eleven molecules of water of crystallization. The relatively coarse-grained salt is then separated by filtration and generally used without drying. For the conversion of calcium hexacyanoferrate(II) to the potassium or sodium salt, two methods are used.

In the first, a stoichiometric amount of potassium chloride is added to the filtered calcium hexacyanoferrate(II) solution and the hexacyanoferrate(II) precipitates as a sparingly soluble potassium calcium double salt [153]

$$Ca_2[Fe(CN)_6] + 2\,KCl \rightarrow K_2Ca[Fe(CN)_6] + CaCl_2$$

The double salt is separated by filtration, redispersed in water, and then converted to the soluble potassium hexacyanoferrate(II) by the addition of potassium carbonate:

$$K_2Ca[Fe(CN)_6] + K_2CO_3 \rightarrow K_4[Fe(CN)_6] + CaCO_3$$

After separation of the insoluble calcium carbonate, the potassium hexacyanoferrate (II) solution is concentrated by evaporation, and the potassium salt crystallizes with three molecules of water of crystallization. After filtration, the salt is

carefully dried and packaged.

A similar method can be used for the production of sodium hexacyanoferrate(II): sodium carbonate is added to the calcium hexacyanoferrate(II) solution and the precipitated calcium carbonate is separated:

$$Ca_2[Fe(CN)_6] + 2\,Na_2CO_3 \rightarrow Na_4[Fe(CN)_6] + 2\,CaCO_3$$

Usually, the sodium hexacyanoferrate(II) is synthesized directly from solutions of sodium cyanide and iron(II) chloride [154]:

$$6\,NaCN + FeCl_2 \rightarrow Na_4[Fe(CN)_6] + 2\,NaCl$$

The crystalline Na_4 [Fe $(CN)_6$] · 10 H_2O can be obtained when the solution is concentrated; it must be dried very carefully to avoid loss of water of crystallization, which would influence its solubility properties.

The disadvantages of the double-salt process are the necessity of recycling the various mother liquors and the formation of large quantities of solid waste products.

In the second conversion method, the hexacyanoferrate(II) is precipitated from a solution of the calcium salt as Berlin white by the addition of iron(II) chloride solution:

$$Ca_2[Fe(CN)_6] + 2\,FeCl_2 \rightarrow Fe_2[Fe(CN)_6] + 2\,CaCl_2$$

This iron(II) hexacyanoferrate(II) is separated by filtration, redispersed in water, and converted to sodium or potassium hexacyanoferrate(II) by the addition of stoichiometric amounts of sodium or potassium cyanide:

$$Fe_2[Fe(CN)_6] + 12\,KCN \rightarrow 3\,K_4[Fe(CN)_6]$$

Potassium hexacyanoferrate(III) can be obtained by the oxidation of potassium hexacyanoferrate(II). Usually, anodic oxidation is applied by means of nickel electrodes [155]:

$$2\,K_4[Fe(CN)_6] + 2\,H_2O \rightarrow 2\,K_3[Fe(CN)_6] + 2\,KOH + H_2$$

Alternatively, hydrogen peroxide can be used for the oxidation of hexacyanoferrate(II) when the reaction is carried out below pH 3 [156]:

$$3\,K_4[Fe(CN)_6] + H_4[Fe(CN)_6] + 2\,H_2O_2 \rightarrow 4\,K_3[Fe(CN)_6] + 4\,H_2O$$

The dry, ruby-red potassium hexacyanoferrate(III) is obtained by concentration of the solution at reduced pressure and crystallization at ca. pH 7. The fact that H_2O_2 reduces hexacyanoferrate(III) to hexacyanoferrate(II) at higher pH must also be considered.

2.3.1.3. *Commercial Forms, Specifications, and Packaging*

The following commercial products are most frequently used:

Sodium hexacyanoferrate(II) [69043-75-0], sodium ferrocyanide, yellow prussiate of soda (YPS), Na_4 [Fe $(CN)_6$] · 10 H_2O, M_r 484.108, ϱ 1.46 g/cm^3, light yellow, monoclinic crystals, readily soluble in water (33.7 g in 100 g H_2O at 20 °C).

Potassium hexacyanoferrate(II) [14459-95-1], potassium ferrocyanide, yellow prussiate of potash (YPP), K_4 [Fe (CN) $_6$] · 3 H_2O, M_r 422.39, ϱ 1.85 g/cm^3, lemon yellow, monoclinic crystals, readily soluble in water (33.7 g in 100 g H_2O at 20 °C).

Calcium hexacyanoferrate(II) [13821-08-4], calcium ferrocyanide, yellow prussiate of calcium (YPC), Ca_2 [Fe (CN) $_6$] · 11 H_2O, M_r 490.296, ϱ 1.68 g/cm^3, yellow monoclinic crystals, highly soluble in water (148.4 g in 100 g H_2O at 20 °C).

Potassium hexacyanoferrate(III) [13746-66-2], potassium ferricyanide, K_3 [Fe $(CN)_6$], M_r 329.25, ϱ 1.858 g/cm^3, orange to ruby red, monoclinic crystals, readily soluble in water (46.4 g in 100 g H_2O at 20 °C).

The commercial products are fine, crystalline, free-flowing powders. Normally, they are packaged in polyethylene bags of 25-kg net weight, and must be stored under cool, dry conditions and kept away from acids. Hexacyanoferrates are not dangerous goods according to appendix C of the EVO, GGVS, RID, ADR, and IMCO Code. The specifications and average analyses for the commercially used hexacyanoferrates are listed in Table 8.

Uses and Economic Aspects. Sodium, potassium, and calcium hexacyanoferrates(II) are equally suitable for use in most applications, but sometimes one product may be preferred. For the production of blue pigments, the most important application of hexacyanoferrates, the potassium salt is used in Europe, whereas the sodium salt is preferred in the United States. Generally, blue hexacyanoferrate(II) compounds are formed by the reaction of iron(III) salts with hexacyanoferrates (II):

$$FeCl_3 + K_4[Fe(CN)_6] \rightarrow FeCl_2 + K_3[Fe(CN)_6] + KCl \rightarrow KFe(III)[Fe(II)(CN)_6] + 3\,KCl$$

The production of blue pigments is more complicated, however, and is based primarily on the oxidation of iron(II) hexacyanoferrate(II) precipitates in the presence of alkali metal or ammonium salts [2]. The properties of blue pigments are not dependent only on the composition; the precipitation method and the finishing of the product are also very important. The use of hexacyanoferrates(II) for the production of classified documents is also based on this reaction. Large amounts of all three types of hexacyanoferrates (II) are used as additives for rock salt to prevent caking [157]; hexacyanoferrates(II) act as crystal growth inhibitors in this application. The ability of hexacyanoferrates(II) to form insoluble or almost insoluble heavy metal compounds is used, e.g., in the production of citric acid by fermentation [158], in the refining of wine [159], in the electroplating of tin [160], and in analytical chemistry. Potassium hexacyanoferrate(III) and alkali hexacyanoferrate(II) combined with peroxodisulfates play an important role as bleaching agents in color photography [151]. Both hexacyanoferrates are also important depressants for the separation of molybdenum from copper by flotation [161].

2.3.2. *Cyanides of Copper, Zinc, and Cadmium*

Properties.

Copper(I) cyanide [544-92-3], CuCN, M_r 89.56, *mp* 473 °C, forms white monoclinic prismatic crystals, ϱ 2.92 g/cm^3, which are insoluble in water, dilute mineral acids, and organic solvents; CuCN is soluble in ammonia and in alkali metal cyanide solution because equilibria are established with highly soluble cyano complexes:

$$CuCN + 2\,NaCN \rightleftharpoons Na_2[Cu(CN)_3] + NaCN$$

(slightly soluble) (slightly soluble)

$$Na[Cu(CN)_2] + NaCN \rightleftharpoons Na_2[Cu(CN)_3] + NaCN \rightleftharpoons Na_3[Cu(CN)_4]$$

(slightly soluble)

These complexes can also be obtained as solids. In the absence of air and moisture, pure CuCN can be stored indefinitely without deterioration.

Zinc cyanide [557-21-1], $Zn(CN)_2$, M_r 117.42, *mp* 800 °C (decomp.), forms a white crystalline powder with a slight HCN odor, ϱ 1.852 g/cm^3 (25 °C), which is insoluble in water but soluble in aqueous solutions of alkali metal hydroxides or cyanides by formation of hydroxy ($[Zn(OH)_4]^{2-}$) or cyano complexes ($[Zn(CN)_4]^{2-}$). In the absence of air, carbon dioxide, and moisture, zinc cyanide can be stored indefinitely without deterioration.

Cadmium cyanide [542-83-6], $Cd(CN)_2$, M_r 164.45, *mp* 200 °C (decomp.), forms white irregular octahedral crystals, ϱ

2.23 g/cm^3 (25 °C), which are soluble in water (1.7 g in 100 g H_2O at 15 °C). Cyano complexes are formed when cadmium cyanide is dissolved in aqueous solutions of alkali metal cyanides: $[Cd(CN)_3]^-$, $[Cd(CN)_4]^{2-}$. In the absence of air and moisture, pure $Cd(CN)_2$ is stable and can be stored indefinitely; in moist air, it decomposes slowly.

Production. The preferred method for the production of copper cyanide is based on the reaction of copper(II) salts, metallic copper, and hydrogen cyanide in hydrochloric acid solution [162], [163]. The reaction solution can be recycled, which avoids environmental problems. The $Cu(CN)_2$ formed when copper(II) salts react directly with alkali cyanide or HCN is unstable and decomposes to CuCN and cyanogen, $(CN)_2$ (see Section Production).

Zinc cyanide can be obtained from the reaction of zinc salts with alkali cyanide in aqueous solution. However, the reaction of zinc oxide with hydrogen cyanide in acetic acid has the advantage that no additional salt is produced [164].

Cadmium cyanide can be produced by evaporation of a solution of cadmium hydroxide in aqueous hydrogen cyanide [165] or by precipitation from a cadmium salt solution with alkali cyanide [166].

Commercial Forms, Specifications, and Packaging. Commercially, CuCN and $Zn(CN)_2$ are supplied as white, fine crystalline powders, packaged in steel drums of 10 kg, 25 kg, and 50 kg net weight. Also 1 t packages, as described for the alkali metal cyanides are available. The specifications and the average analyses are shown in Table 9.

Water-soluble, complex copper and zinc cyanides, as well as mixtures of CuCN and $Zn(CN)_2$ with alkali metal cyanides (containing ca. 23 or 29 % Cu or 23 % Zn), are available for use in electroplating processes.

For transportation, storage, and handling, the same precautions must be observed as for alkali metal cyanides.

Uses and Economic Aspects. The simple cyanides of copper and zinc are used primarily in combination with alkali metal cyanides in bath formulations for the electroplating industry. The main applications are copper, zinc, and brass plating.

Copper(I) cyanide is an important reagent for the introduction of cyano groups into aromatic rings to produce benzonitrile derivatives (Sandmeyer reaction). Furthermore, it is used in the synthesis of insecticides and fungicides [167], in the preparation of special paints for ships, as a catalyst for the polymerization of organic compounds, and for the synthesis of anticancer drugs. Copper and zinc cyanide are used in the production of phthalocyanine dyes.

2.3.3. *Cyanides of Mercury, Lead, Cobalt, and Nickel*

The cyanides of mercury, lead, cobalt, and nickel do not have any major industrial importance. Water-soluble complex cyanides can be obtained by the reaction of the simple cyanides with alkali metal cyanides.

Properties, Preparation, and Uses.

Mercury(II) cyanide [3021-39-4], Hg $(CN)_2$, M_r 252.65, ϱ 4.0 g/cm^3, forms white crystals, which are very soluble in water; it is highly toxic. The substance can be prepared by the reaction of HgO with aqueous HCN. When heated, it decomposes to Hg and $(CN)_2$, and may explode if detonated [165], [168]. The complex salts Na [Hg $(CN)_3$], M_r 301.66, and K_2 [Hg $(CN)_4$] [591-89-9], M_r 382.87, are white crystalline powders which are very soluble in water. Mercury (II) oxide cyanide [2040-54-2], Hg $(CN)_2 \cdot$ HgO, M_r 469.26, is less stable and more sensitive to shock than picric acid [169].

Lead cyanide [13453-58-2], $Pb(CN)_2$, M_r 259.25, can be obtained by the reaction of aqueous solutions of lead salts and alkali metal cyanides in the presence of HCN [2]. In the absence of HCN, oxide cyanides are formed, e.g., $Pb(CN)_2 \cdot 2$ PbO.

Cobalt(II) cyanide [542-84-7], Co $(CN)_2 \cdot 2\ H_2O$, M_r 110.95, *mp* 280 °C (decomp.), ϱ 1.872 g/cm^3, forms red-brown needles which are insoluble in water. It can be obtained by the reaction of aqueous solutions of cobalt salts and alkali metal cyanides, and can be converted to soluble complex compounds with ammonia or excess alkali metal cyanide.

Complex cobalt(III) cyanides are formed when solutions of complex cobalt(II) cyanides are heated in the presence of oxygen:

$$2\,K_4[Co(CN)_6] + H_2O + 1/2\,O_2 \rightarrow 2\,K_3[Co(CN)_6] + 2\,KOH$$

Cobalt cyanides are among the most stable complexes; therefore, cobalt compounds have been used as antidotes for cyanide poisoning [170].

Nickel cyanide [557-19-7], Ni $(CN)_2$, M_r 110.74, *mp* > 200 °C (decomp.), ϱ 2.393 g/cm^3, forms brownish-yellow crystals which are insoluble in water. It can be obtained by the dehydration of Ni $(CN)_2 \cdot 4\ H_2O$, which is precipitated when alkali metal cyanide is added to a solution of a nickel salt.

Potassium tetracyanonickelate(II) monohydrate [14323-41-2], K_2 [Ni $(CN)_4$] $\cdot\ H_2O$, M_r 258.97, forms orange-red crystals which are very soluble in water. The complex salt is formed when excess KCN is employed in the preparation; K_2 [Ni $(CN)_4$] is used as an additive to electrolytes in the plating of gold, silver, and zinc, to improve the quality of the deposits.

2.3.4. *Cyanides of Precious Metals*

The precious metal cyanides can be regarded as the historical starting point of inorganic cyanide chemistry. Their importance for the recovery, refining, and electroplating of precious metals is as great today as it was 100 years ago.

Gold(I) cyanide [506-65-0], AuCN, M_r 222.98, ϱ 7.12 g/cm^3, forms yellow crystals which are insoluble in water and hot dilute acids, but soluble in ether, alkali metal hydroxide, and thiosulfate solutions. Water-soluble [Au $(CN)_2]^-$ complexes are formed when AuCN is dissolved in alkali metal cyanide solution or when gold metal is attacked by alkali metal cyanide in the presence of oxygen or oxidizing agents.

Silver(I) cyanide [506-64-9], AgCN, M_r 133.89, *mp* 320 °C (decomp.), ϱ 3.95 g/cm^3, forms white hexagonal crystals which are insoluble in water but soluble in aqueous alkali metal cyanide solution, forming complex [Ag $(CN)_2]^-$ compounds. Like AgCl, AgCN becomes brown if exposed to light. The production of AgCN is based on the reaction of $AgNO_3$ with alkali metal cyanide in aqueous solution. Its main application is in electroplating.

Palladium(II) cyanide [2035-66-7], $Pd(CN)_2$, M_r 158.7, *mp* 210 °C (decomp.), is soluble in water.

Platinum(II) cyanide [592-06-3], $Pt(CN)_2$, M_r 247.27, is insoluble in water and dilute acids. Both palladium(II) cyanide and platinum(II) cyanide can be prepared from the corresponding chlorides by precipitation with Hg $(CN)_2$. Tetracyano complexes are formed with excess alkali metal cyanide: K_2 [Pd $(CN)_4$] $\cdot$ 3 H_2O forms white rhombohedral fluorescent crystals, and K_2 [Pt $(CN)_4$] $\cdot$ 3 H_2O forms rhombic yellow prisms with blue fluorescence. The barium salt Ba [Pt $CN)_4$] $\cdot$ 4 H_2O is used to prepare the fluorescent coating of X-ray screens; the alkali metal tetracyanoplatinates are used in electroplating. The unstable Pd $(CN)_4$ is also known.

2.4. Cyanide Analysis

The cyanide content of solid alkali metal cyanides, alkaline earth metal cyanides, and dissociating heavy metal cyano complexes such as $[Zn(CN)_4]^{2-}$ may be determined by the argentometric titration of a dilute aqueous solution of the cyanide, according to the method of Liebig – Denigés, in which potassium iodide is used as an indicator [171]:

$$2\,CN^- + Ag^+ \rightarrow [Ag(CN)_2]^-$$

A very accurate indication of the end point of this reaction can be obtained potentiometrically by using a silver – calomel or silver – Thalamide (Schott Glaswerke, Mainz) electrode pair. This method of determination is called the determination of free cyanide and is also an important parameter in the leaching of gold and silver ores.

For more stable cyano complexes or insoluble cyanide compounds [e.g., iron(II) hexacyanoferrate(II)] or in the presence of substances that disturb the argentometric titration, liberation and separation of the cyanide must be carried out before

determination. This can be done by acidifying and boiling the cyanide solution or suspension, and absorbing the released hydrogen cyanide in sodium hydroxide solution [172]. Depending on the concentration, the cyanide content of the absorption solution may be analyzed argentometrically or colorimetrically, e.g., by using pyridine-barbituric acid reagents [173]. This method of determination is called the determination of total cyanide, because all except extremely stable cyanide complexes, such as that of cobalt, liberate cyanide for determination. There is an ISO standard for total cyanide determination (ISO/DIS 6703/1) [174]. The ASTM determination method for total cyanide is also used internationally [175].

To evaluate the toxicity of wastewaters and effluents that contain cyanide, readily liberable cyanide (ISO/DIS 6703/1) is a reliable method for determining less stable complexes of cyanide. Hydrogen cyanide, alkali and alkaline earth metal cyanides, and the cyanides of zinc, cadmium, silver, mercury, copper, and nickel are determined by this method. The complex cyanides of iron, cobalt, gold, and nitriles [174] are not amenable to this method. In this method, hydrogen cyanide is liberated at pH 4 in the presence of zinc metal and ethylenediaminetetraacetic acid. The HCN is transferred to an absorption vessel and analyzed argentometrically or colorimetrically. The ASTM method for the determination of less stable complexes of cyanide is called the weak acid-dissociable cyanide method [175]. Another fast determination method of cyanide analysis, similar to the above two distillation methods, is the colorimetric picric acid method [176]. This method has gained in popularity since the 1970s, it yields very similar results to the above two standard methods but is much quicker. This is important, where effluents are discharged continuously (e.g., gold mine effluent).

Other cyanide determination methods such as the colorimetric method with pyridine – barbituric acid reagents [173] and ion-selective electrode [177] methods for free cyanide are prone to interference by various substances. The ion-chromatographic method has been a subject of research since the 1980s, and techniques have been developed to determine several cyanide species selectively, especially at low concentrations. However, these techniques and instrumentation have not yet achieved widespread application [177].

Quick tests to check the concentration of cyanides in wastewater are based on various colorimetric methods [173], [176]. Generally, the reactions permit detection of very small amounts of free cyanide, but they can be disturbed by various substances, e.g., reducing agents or thiocyanate, sulfide, and nitrite, which all produce similar colors.

[Top of Page]

3. Detoxification of Cyanide-Containing Wastes

Whenever cyanides are manufactured or used, effluents and wastes containing various amounts of cyanide are produced. Because of the high toxicity of cyanide to all forms of life (see Chap. Toxicology and Occupational Health), the effluents and wastes must be treated to reduce the cyanide content to concentrations that are acceptable with the regard to the particular environmental conditions [178-182]. Depending on the quantity and type of cyanidic waste, various detoxification methods are used [183-187]. In addition to effectiveness and cost of treatment, the formation of undesirable byproducts and additional salting of the wastewater are factors of growing importance in choosing an effluent-treatment method.

Heavy metals may be precipitated and separated as hydroxides, carbonates, or sulfides, when complex heavy metal cyanides are oxidized. Wastewater treatment can be carried out batchwise or continuously, and the process may be monitored and controlled automatically.

3.1. Wastewater Treatment

Chlorination. Alkaline chlorination is the most frequently used process for the treatment of effluents containing < 1 g CN^- per liter [188]. In principle, this method allows the destruction of all commercially used simple and complex cyanides, with the exception of complex iron cyanides, which are only attacked above 80 °C. The treatment can be carried out with chlorine and alkali [NaOH, $Ca(OH)_2$] or with readymade hypochlorite solutions that contain about 12 % NaOCl. At first, toxic cyanogen chloride is formed, which is hydrolyzed quickly to cyanate and chloride at pH > 11 [189]:

$$CN^- + OCl^- + H_2O \rightarrow ClCN + 2\,OH^-$$

$$ClCN + 2\,OH^- \rightarrow OCN^- + Cl^- + H_2O$$

Additional salting of the water is the main disadvantage of alkaline chlorination: at least 5 kg of NaCl is produced per kilogram of cyanide for the oxidation of cyanate, and an additional 6.5 kg of NaCl per kilogram of cyanide results from total oxidation [190]. Alkaline chlorination is frequently used for the treatment of smaller quantities of effluent and less for large continuous operations. It is frequently used, for example, in the detoxification of electroplating effluents, when permissible. Lower chloride limits in the treated effluent make an alternative process necessary. Hypochlorite solutions tend to lose their active oxygen content relatively fast.

Hydrogen Peroxide Oxidation. The use of hydrogen peroxide for cyanide detoxification has increased because, in this case, the oxidation of cyanide leads directly to cyanate without the formation of toxic intermediates and byproducts, and the oxidant does not cause additional salting [190], [191]:

$$CN^- + H_2O_2 \rightarrow OCN^- + H_2O$$

The H_2O_2 process is used mainly for the batchwise treatment of effluents from organic nitrile synthesis and metal hardening plants, and can be monitored and controlled automatically [192], [193]. One process allows delivery of accurate amounts of H_2O_2 to continuous effluent streams, which is controlled by on-line measurement of the total oxygen demand [194]; this process is used, for example, in the treatment of tailings from gold mines [177], [195]. More recently, the H_2O_2 process has increasingly found applications in the seasonal detoxification of effluents from gold mines, because of the ease of operation and relatively low investment costs. The H_2O_2 process has been optimized by the addition of compounds that reduce the

quantitiy of H_2O_2 required [196].

Other Methods of Treatment. A method from 1982 is based on the treatment of effluents with a mixture of sulfur dioxide (2.5 %) and air in the presence of small amounts of copper salts (> 50 mg Cu per liter) as catalyst [202]:

$$CN^- + O_2 + SO_2 + H_2O \rightarrow OCN^- + H_2SO_4$$

This is called the Inco process. The detoxification of cyanide-containing pulps is becoming more and more important. In addition to the Inco process method above, the Caro's acid process is also used to create cyanide-containing pulps according to the reaction:

$$CN^- + H_2SO_5 \rightarrow OCN^- + H_2SO_4$$

A further development uses the synergies between the Inco process and the Caro's acid or hydrogen peroxide process to detoxify cyanide-containing slurries more efficiently. This process is called the CombiOx process [203].

In the case of highly concentrated cyanide solutions, the volatilization and catalytic oxidation of HCN after acidification of the solutions can be used [186]. Sometimes, the hydrogen cyanide can be reused by absorption in alkali metal hydroxide solution and conversion to alkali metal cyanide. Atmospheric oxygen is occasionally used for the destruction of cyanide in weak solutions, in combination with activated carbon [97], [198] or microorganisms [199]. Removal of cyanides by ion exchange and reverse osmosis does not solve the problem entirely because the concentrates require further treatment [200], [201].

The hydrolysis of cyanide at 180 – 230 °C under pressure can be used for the destruction of simple and complex cyanides, even in high concentrations [94]. The process does not require chemicals, but the investment for the plant is high.

The conversion of cyanide to thiocyanate by the addition of sulfur is a process that used to be employed but is now regarded more critically [183]. This process has the advantage of low reagent costs, but the investment for plant can be high. It is less suitable for seasonal detoxification, since start up and decommissioning can take time.

Very effective oxidation of cyanide to cyanate, carbonate, and nitrogen takes place with ozone [94], [197]; however, this requires high capital investment and causes problems with the adaptation to varying oxygen demand.

The conversion of cyanide to hexacyanoferrate(II) by reaction with iron(II) salts in alkaline solution followed by precipitation of hexacyanoferrate(II) as iron(II) hexacyanoferrate(II) at pH 3 – 4 is one of the oldest methods for cyanide removal [204]. However, this should be used only for the removal of complex iron cyanides, if at all, because the sludge must be disposed of in such a manner that water resources are protected. Furthermore, the filtrates must be treated again to destroy the remaining traces of cyanide.

In many cases, low concentrations of complex iron cyanides (e.g., < 20 mg of cyanide per liter) in effluents discharged to sewage systems are tolerated because they are precipitated in contact with metal salts (e.g., the iron salts present in domestic wastewater) and are separated with the sludge of municipal sewage treatment plants.

3.2. Solid Wastes

For a long time, disposal of the solid wastes from metal hardening plants, which contain alkali metal cyanides, cyanates, nitrites, and nitrates in addition to other inorganic salts, was a special problem [84], [85]. New processes have been developed that, in many cases, allow regeneration of waste salts. In any case, solid wastes should not be treated or destroyed by a wet chemical process. The safest and most practical solution to the disposal problem at the present time is to deposit them in disused salt mines.

[Top of Page]

4. Cyanogen Halides

Halogen cyanides, usually known as cyanogen halides, have been the subject of considerable interest, and some aspects of their chemistry have been reviewed in detail [2], [6-11]. These compounds, except for cyanogen fluoride, have been known for a long time [205], [206]. Cyanogen fluoride was prepared in 1981 [207], [208]. Depending upon the electronegativity of the halogens relative to the cyanide group, the cyanogen halides can act as halogenating or cyanating agents. The cyanogen halides can be regarded as pseudohalogen or interhalogen compounds with a definite nitrile structure (X–C≡N) [209]. The most important cyanogen halide is cyanogen chloride, which is used for the commercial production of cyanuric chloride, a starting material for pesticides, dyes, and drugs (⟶).

4.1. Properties

Physical Properties. The pure cyanogen halides are colorless, highly volatile, and poisonous compounds. Some physical properties are given in Table 10.

Table 10. Physical properties of the cyanogen halides [10], [11], [209]

	FCN [1495-50-7]	ClCN [506-77-4]	BrCN [506-68-3]	ICN [506-78-5]

* Triple point, *p* = 132.1 kPa; subl. = sublimation.

Chemical Properties. Pure cyanogen halides are stable at normal temperature. Impurities catalyze the exothermic trimerization to the corresponding cyanuric halides. Catalysts are proton acids, Lewis acids (e.g., heavy metal salts), and bases. Relatively little is known about the preparative use of FCN [208], which explodes at – 41 °C on ignition. Mixtures of FCN and air are more explosive than mixtures of acetylene and air [210]. In a catalytic reaction, ClCN forms not only the trimer (cyanuric chloride [108-77-0]) but also a stable tetramer, 2,4-dichloro-6-isocyanodichloro-*s*-triazine [877-83-8] [211].

Cyanogen bromide polymerizes more readily to cyanuric bromide [14921-00-7] than does ClCN to cyanuric chloride [212].

When heated to 130 °C in a sealed tube, cyanogen iodide does not polymerize [213]. Above 150 °C, ICN eliminates iodine:

$$2\,ICN \rightarrow (CN)_2 + I_2$$

The reaction is not reversible [214].

Cyanogen chloride is an intermediate in the detoxification of cyanide-containing wastewater with sodium hypochlorite solutions; therefore, the cyanogen halide must be removed immediately by appropriate hydrolysis [215]. Alkaline hydrolysis of cyanogen halides proceeds in different ways:

$$XCN + 2\,NaOH \rightarrow NaOCN + NaX + H_2O (X = Cl\,, Br)$$

$$ICN + 2\,NaOH \rightarrow [NaOI] + NaCN + H_2O$$

Thus, ClCN and BrCN are hydrolyzed to the cyanate and halide salts; ICN, however, forms hypoiodite, which disproportionates to iodide and iodate. This is due to the more electropositive character of iodine relative to chlorine [11]. Therefore, ClCN can be used for the electrophilic introduction of a cyano group into a substrate; use of ICN results in electrophilic iodination. The reaction pathway of BrCN often depends on the reaction conditions and on the nature of the substrate [216]. Cyanogen halides add to olefins and acetylenes in the presence of acid catalysts [217], [218]. Aromatic ring systems can be cyanated by ClCN or BrCN under Friedel – Crafts conditions [209], [220]. The reactions of cyanogen halides, particularly ClCN and BrCN, with nitrogen, oxygen, and sulfur nucleophiles lead to cyanamides [221-223] cyanates [224], [225], and thiocyanates [226].

In some cases, the newly formed compound undergoes further reactions at the C≡N triple bond to form guanidines [221], [222], ureas, or heterocyclic ring systems [227]. Cyanogen bromide reacts with tertiary alkylamines to form ammonium bromides, which decompose to give dialkyl cyanamides and alkyl bromides (von Braun reaction) [228], [229]. Reaction of sulfur trioxide with ClCN leads to the very reactive chlorosulfonyl isocyanate [230], [231]. Cyanogen halides undergo radical reactions at elevated temperatures on irradiation with UV light or in the presence of peroxide promoters. Thus, cyanogen chloride and acetonitrile are converted to malonodinitrile [232-235]. In the gas phase, aromatic methyl compounds and cyanogen chloride react to give arylacetonitriles [236].

4.2. Production

Cyanogen fluoride is prepared by the reaction of tetracyanomethane with cesium fluoride [237]:

$$C(CN)_4 + CsF \rightarrow FCN + CsC(CN)_3$$

The pyrolysis of cyanuric fluoride at 1300 °C under reduced pressure gives FCN in ca. 50 % yield [207], [208], [210].

The preparation of the industrially important ClCN has been developed extensively; the synthetic pathways are as follows:

1. Electrolysis of an aqueous solution of HCN and NH_4Cl [238]
2. Reaction of complex cyanide salts (e.g., Na_2 [Zn $(CN)_4$]) with chlorine below 20 °C [239]
3. Formation of ClCN from cyanide salts (mostly NaCN) and chlorine in an exothermic reaction; in a continuous process, sprayed aqueous NaCN solution is contacted with chlorine, and the reaction heat evaporates the ClCN [240].
4. Processes involving hydrogen cyanide and chlorine as the most convenient starting materials; the reaction is carried out in aqueous solution [241-246] (for a detailed procedure, see also ⟶) in organic [247] and inorganic solvents [248], and in the gas phase [249], [250]. To avoid the byproduct HCl, attempts have been made to reoxidize HCl to chlorine with oxygen [245] and hydrogen peroxide [251], [252] in catalyzed reactions.
5. Chlorinolysis of cyanogen in the gas phase at 300 – 600 °C in the presence of a catalyst [253], [254]
6. Pyrolysis of cyanuric chloride at 600 – 900 °C in the presence of a charcoal catalyst [255]
7. High-temperature syntheses based on elemental chlorine, nitrogen, and carbon [256]

Usually, these processes lead to impure ClCN; therefore, in many cases the product must be purified before further use. Water can be removed by treatment with calcium salts or molecular sieves and by fractional distillation [257]. Chlorine is stripped with water (mixed with HCN and HCl) [258] or with solutions containing a soluble iron(II) salt and an insoluble carbonate [259]; chlorine may also be eliminated by treatment with γ-aluminum oxide [260]. Cyanogen chloride, free of HCl, is obtained by treatment with water [258] or with organic solvents [261], [262]. Hydrogen cyanide is removed by distillation with chlorine [263] or by washing with $FeSO_4$ solutions [264].

Cyanogen bromide can be prepared from bromine and cyanide salts or hydrogen cyanide [265], [266]. Cyanogen iodide is synthesized analogously [267], [268].

4.3. Storage and Transportation

In most cases, ClCN is used in the gas phase immediately after preparation. Relatively small amounts are condensed and stored in gas containers as liquids. Steel cylinders, which must meet specific requirements in each country, can be used for shipment. The condensed and bottled ClCN must be very pure; moreover, it must be mixed with a stabilizing agent (generally sodium pyrophosphate) to inhibit exothermic polymerization caused by impurities [269-271]. Impure BrCN can polymerize during storage [272]; the danger of explosion exists with closed BrCN bottles [273]. Cyanogen halides should be handled carefully because they are very toxic (similar to HCN) and have a strong lacrimatory effect.

4.4. Uses

Most of the cyanogen chloride is used for the production of cyanuric chloride. The reaction with amines leads to diphenylguanidines (vulcanization accelerators) [274]. Cyanogen chloride and bisphenols react to give cyanate esters, which can polymerize to polytriazine resins [224], [225].

Halogen cyanides and cyanamide react to form dicyanamide [504-66-5] [275], [276], which is used for the preparation of pharmaceutical bisbiguanides. The industrial production of malonodinitrile [109-77-3] [232-235], and chlorosulfonyl isocyanate [1189-71-5] [230], [231] based on cyanogen chloride has become increasingly important. Cyanogen chloride is the most economically significant of all cyanogen halides. Its worldwide production capacity is more than 230 000 t/a (mainly in Europe and the United States).

Cyanogen bromide and cyanogen iodide are commonly used in the laboratory, e.g., for the dealkylation of tertiary amines [228], [229], the selective cleavage of peptides [277], and the preparation of heterocyclic compounds.

[Top of Page]

5. Cyanogen

The first synthesis of cyanogen [460-19-5], dicyanogen, oxalonitrile, $(CN)_2$, M_r 52.05, was carried out by GAY-LUSSAC in 1815 by pyrolysis of silver cyanide [264]. The chemistry of this reactive compound is discussed in [1], [12-17]. In many respects, cyanogen can be compared to the halogens. In addition, many of its properties are a result of the reactivity of the cyano groups. Although various procedures for the synthesis of cyanogen are known, commercial interest in cyanogen is limited.

5.1. Properties [1], [17]

Physical Properties. At room temperature, cyanogen is a colorless, flammable, and very poisonous gas with a pungent odor. Some important physical properties are listed below:

Melting point	–27.98 °C
Boiling point	–21.15 °C
Critical pressure, $p_{crit.}$	60.79 bar
Critical temperature, $t_{crit.}$	128.3 °C
Density	2.321 g/L at 0 °C
	1.25 g/cm^3 at –95 °C

0.954 g/cm^3 at –21.17 °C

Vapor pressure

t, °C	–21.15	–4.88	20.88	44.43	72.40
p, bar	1	2	5	10	20

Solubility at 20 °C: water dissolves 4.5 times its own volume of cyanogen; diethyl ether, 5.0 times; and ethanol, 23.0 times.

Bond length:	
C–C	138 pm
C–N	113 pm
Bond angle: C–C–N	179° 38′
Enthalpy of fusion, ΔH_f	8.112 kJ/mol
Enthalpy of vaporization	23.341 kJ/mol
MAK	10 ppm

The values reported for the ignition limits of cyanogen – air mixtures vary widely, depending on experimental conditions, e.g., with humid air (1.7 % H_2O); the reported values are 6.4 – 7.25 vol % for the lower limit, and 26.2 – 30.6 vol % for the upper limit.

Chemical Properties. Cyanogen has a high thermal stability; nevertheless at high temperatures (and when irradiated with UV light), polymerization to paracyanogen occurs [17], [279], [280]. With stoichiometric amounts of air or oxygen, cyanogen burns with the hottest flame (ca. 5000 K) ever observed in chemical reactions [281], [282].

Cyanogen undergoes reactions which depend either on its properties as a pseudohalogen or on the reactivity of the C≡N triple bond [1], [15], [17]:

1. Hydrogenation of cyanogen at 550 – 675 °C gives hydrogen cyanide [283].
2. At 300 – 500 °C, chlorine and cyanogen react to give cyanogen chloride and, subsequently, cyanuric chloride in the presence of an active charcoal catalyst [284], [285].
3. The direct introduction of a cyano group into an aryl or alkyl compound proceeds via a radical- or heat-initiated reaction [286-289].
4. Two moles of hydrogen cyanide add to cyanogen to form diiminosuccinonitrile [290].
5. Cycloadditions (Diels – Alder) with organic dienes give cyanopyridines [291].
6. Alkaline hydrolysis leads to cyanide and cyanate [292].
7. The acid-catalyzed hydrolysis of cyanogen first gives cyanoformamide [293], [294] and then oxamide and oxalic acid. Oxamide [471-46-5] is a nitrogen fertilizer with good depot activity. Its industrial preparation has been published in several papers; most of the synthetic paths use the isolated $(CN)_2$ as an intermediate [295-300], but in situ procedures are also known [301].

Heterocyclic compounds are formed by the reaction of cyanogen and disulfur dichloride [302] or sulfur [303]:

5.2. Production

Numerous synthetic pathways to cyanogen have been devised [1], [13], [15], [17]. In the laboratory, the compound is normally prepared via cyanide salts; in this case, the reaction of alkali metal cyanides with copper(II) salts is more common than the thermal decomposition of $Hg(CN)_2$ or AgCN [17].

$$CuSO_4 + 2\,KCN \rightarrow Cu(CN)_2 + K_2SO_4$$

$$2\,Cu(Cu)_2 \rightarrow (CN)_2 + 2\,CuCN$$

However, the oxidation of hydrogen cyanide in the presence of a catalyst has greater industrial interest. These reactions are based on the principle of JACQUEMIN [304], that is the conversion of cyanides, by treatment with copper salts, to cyanogen in aqueous solution. In a continuous process, the copper(I) salt formed must be reoxidized rapidly to recycle the catalyst. Reoxidation of copper(I) to copper(II) can be carried out directly with air or oxygen [305], [306] or with NO_2 [307] the NO formed in the second case can then be reoxidized with air or oxygen [308], [309]. The oxidation of hydrogen cyanide to cyanogen in nonaqueous solutions has also been achieved [310], [311]. Hydrogen peroxide is another reoxidation agent [312-315].

The continuous production of $(CN)_2$ from HCN and O_2 or H_2O_2 is utilized industrially on a small scale.

In addition to the liquid-phase oxidation of HCN, various gas-phase oxidations have been investigated [316-321].

Cyanogen iodide decomposes to cyanogen and iodine (Chap. Cyanogen Halides). In 1984 the reaction of cyanogen halides with trimethylsilyl cyanide in the presence of Lewis acids has been described [322].

Cyanogen prepared by the above procedures contains impurities such as O_2, N_2, NO, CO_2, or ClCN. Its purification can be achieved by fractional vaporization of the crude material [323] or by scrubbing the gas with aqueous H_2O_2 [324].

5.3. Storage, Transportation, and Uses

Storage and Transportation. The flammability and toxicity of cyanogen necessitate special storing and shipping conditions. Cyanogen should be stored in cool, well-ventilated locations, not near to flammable goods or open flames. Dry and pure $(CN)_2$ can be stored in steel cylinders under pressure and at normal temperatures [325]. Comprehensive studies have been made on the stability of pure cyanogen to heat, pressure, chemical additions, and severe mechanical shock [326]. Shipment must be in accordance with governmental regulations in each country.

Uses and Economic Value. Cyanogen is used mainly in the laboratory. In small quantities, cyanogen is used industrially for drug synthesis. The preparation of oxamide (a slow-release fertilizer) has been carried out on a small scale [285]. Large-scale industrial applications are not yet known.

6. Toxicology and Occupational Health

Toxicity and Cyano Compounds. Hydrogen cyanide and other cyano compounds that can form HCN or free cyanide ions are highly toxic to most forms of life. The lethal dose depends on a number of factors, and differs from species to species. A useful survey on this subject can be found in [181]. As shown in this report, the toxicity of metal cyanide complexes is a function of the bond strength between the metal atoms and the cyanide ligands. Toxicity decreases with increasing bond strength, and complexes such as hexacyanocobalt(II) are nontoxic. Hexacyanoferrates(II) and (III) also have very low toxicities [327]. These differences in toxicity are particularly important when the acceptable concentrations of cyanides in wastewater are being considered. Some of the lethal concentrations are shown in Table 11. The LD_{50} values of complex hexacyanoferrates (rat, oral) are as follows:

$Ca_2\,[Fe\,(CN)_6\,] \cdot 11\,H_2O$ > 5110 mg/kg

$Na_4\,[Fe\,(CN)_6\,] \cdot 10\,H_2O$ > 5110 mg/kg

$K_4\,[Fe\,(CN)_6\,] \cdot 3\,H_2O$ 3613 mg/kg

$K_3\,[Fe\,(CN)_6\,]$ 3503 mg/kg

Table 11. Lethal concentrations of some cyanides (in mg/L)

Substance	Species		
	Fish	*Daphnia magna*	*Escherichia coli*
NaCN	0.05 (5 d) [328]	3.4 (48 h) [329]	0.0004 – 0.1 [330]
NaCN	0.3 – 0.7 (96 h) [331]		
NaCN	1.0 (20 months) [332], [333]		
$K_3[Cu\,(CN)_4\,]$ [334]	1.0	0.8	2500
CuCN	2.2 [179]		
$K_2[Zn\,(CN)_4]$ [334]	0.3	13.5	625

$Zn(CN)_2$	0.2 – 0.3		
$K_2[Cd(CN)_4]$ [334]	0.75	0.5	250
$Cd(CN)_2$	0.17 [179]		
$K_2[Ni(CN)_6]$ [334]	30	75	5000
$Na_4[Fe(CN)_6]$	500 [179]	> 600 [336]	> 1000 [335]

Poisoning by Hydrogen Cyanide and Alkali Metal Cyanides. Hydrogen cyanide is easily absorbed, even through intact skin and mucous membranes. Not even full respiratory protection can prevent hydrogen cyanide from penetrating into the organism. The speed of absorption of orally ingested cyanide depends on the contents of the stomach and gastric pH; empty stomach and low pH lead to rapid absorption of cyanide. Symptoms [337] of the poisoning may vary somewhat, depending on the quantity of hydrogen cyanide absorbed or the quantity of cyanide ingested. Low concentrations of hydrogen cyanide irritate the nasopharyngeal cavity; occasional complaints involve headache, anxiety, and nausea. Rapid inhalation of the lethal dose (ca. 50 – 100 mg) of hydrogen cyanide results in collapse of the individual. This apoplectiform syndrome, characterized by a short spasmodic stage with subsequent respiratory paralysis, results in immediate death. Poisoning symptoms following oral ingestion of cyanides, on the other hand, exhibit a slow progress, even with large doses (150 – 250 mg), because of the slow release of hydrogen cyanide. Case histories described in the literature involve poisoning durations up to several hours. Cyanide affects many enzymes. The inhibition of cytochrome c oxidase is responsible for the acute effects and the marked metabolic changes (lactic acidosis). As in other intoxication, treatment includes the support of vital signs (supportive therapy), prevention of further poison absorption, and enhancement of poison elimination. The administration of antidotes in severe cyanide poisoning is mandatory, although this opinion has been contradicted.

The following concentrations of hydrogen cyanide and other cyanides in air are considered acceptable at the workplace:

TLV–TWA	(hydrogen cyanide)	10 mg/m^3 [338]
MAK	(hydrogen cyanide)	11 mg/m^3 [339]
TLV–TWA	(cyanide dust, as CN)	5 mg/m^3 [338]
MAK	(cyanide dust, as CN)	5 mg/m^3 [339]

Therapy for Poisoning by Hydrogen Cyanide and Other Cyanides. Different antidotes or combination of antidotes are preferred in different countries. The mechanisms of antidotal action follow different principles:

1. Direct complexation of the cyanide and excretion as cyanide – antidote complex (hydroxocobalamin, dicobalt edetate)
2. Methemoglobin-forming compounds which shift the cyanide from the intracellular to the blood compartment [amyl nitrite, sodium nitrite, 4-dimethylaminophenol (4-DMAP)]
3. Sulfate donors, which enhance the natural pathway of detoxification (thiosulfate).

The first aid given to victims of hydrogen cyanide poisoning is not fundamentally different from the measures taken in other acute emergencies. The success of the treatment, however, depends on the immediate start of antidote therapy. Seconds may determine the success or failure of the treatment of cyanide poisoning. The therapeutic measures required depend on the particular poisoning syndrome encountered. The initial treatment is of supreme importance and must be aimed at safeguarding vital functions such as respiration and circulation.

Cyanogen Chloride, Cyanogen Bromide [337]. Because of their high volatility, cyanogen chloride and cyanogen bromide are strong irritants to mucous membranes (eyes, lungs). Their effects are essentially identical to those produced by hydrogen cyanide; however, they are rarely encountered because the irritating effects serve as a warning of potential danger. When handling liquid cyanogen chloride, attention must be paid to the potential for skin absorption. The exposure limit of cyanogen chloride (TLV – TWA) is 0.6 mg/m^3 [338]. The therapy is analogous to that for hydrogen cyanide poisoning.

Cyanogen [337]. Cyanogen irritates mucous membranes and is probably hydrolyzed in the organism to hydrogen cyanide and cyanic acid. The symptoms are similar to those produced by hydrogen cyanide poisoning.

TLV – TWA	20 mg/m^3 [338]
MAK	22 mg/m^3 [339]

The therapy is analogous to that for hydrogen cyanide poisoning.

7. Responsible Care and Product Stewardship

Responsible application is achieved by minimizing losses of reagent and avoiding negative impact on the environment as well as adopting a Responsible Care philosophy to the application of cyanide. This is a complex system with a greater commitment than simply avoiding reagent losses for economic purposes. The purpose of Responsible Care is to increase the

awareness of people involved in cyanide production, transportation, storage, and application to prevent any incidents/accidents. The economic losses which can arise by not adopting a suitable safety program have long been realized by practically all industries. Important factors influencing safety behavior are

- Responsible Care philosophy
- Internal safety program
- Legislation
- Common sense
- Individual behavior

These factors can interact and overlap, and one factor may overrule another, for example, a company safety program may be more stringent than local legislation.

Risks involved in handling cyanide can be categorized into intentional and unintentional misuse. Intentional misuse (e.g., the use of cyanide in fishing) can only be prevented by strict control of the end user or by implementing strict laws. Unintentional misuse, meaning any accident or incident occurring due to the lack of knowledge about how to handle cyanides in a proper manner, or even more important due to an insufficient overview of possible risk situations that might arise, can be avoided by education and increasing the awareness of how to handle this toxic chemical. For example, the formation of hydrocyanic acid is a potential risk in all cyanide-using industries if cyanides are transported together with acids on a truck.

All cyanides and cyanide complexes should be treated with caution. Even stable cyanide complexes like ferro- and ferricyanides, which are relatively nontoxic, can potentially lead to a generation of hydrocyanic acid if they come into contact with strong acids, or even weaker acids over a long time period.

Concentration is also very important, that is, it is important to differentiate between an absolute amount of cyanide that can cause a serious incident and amounts that do not potentially lead to a serious incident.

The risk of a cyanide accident with acids in the gold mining industry is relatively low compared to other industries, since there is a lower risk of acid contact with cyanides. In the electroplating industry it is common practice to use acid baths in combination with cyanide baths. These electroplating lines are sometimes in the same area, without separation (e.g., by a wall). Even more important is that cyanides and acids might be transported to the site on the same truck, and in the case of a road accident HCN could be formed. In the metal-hardening industry, high temperatures are applied, for example, in the Durferrit process. The higher temperatures also represent a potentially higher risk.

A safety cycle describes how the responsibilities in the use of cyanide can be shared between the cyanide user and the cyanide manufacturer. Safe and environmentally friendly production, packaging, and transport are the responsibilities of the cyanide manufacturer. The cyanide user should also take responsibility for that part of the transport which is no longer in the hands or control of the cyanide manufacturer. In addition, the cyanide user should provide safe storage and handling areas and for responsible disposal of the cyanide and of the packing. The cyanide manufacturer should provide the user with the necessary information to enable him to implement his share of the responsibility. Cyanide manufacturers should perform site survey and safety training for their customers to guarantee a dynamic process and eliminate any weak points with regard to Responsible Care. The following are the main points of interest in such a site survey or safety training:

- Storage
- Safe handling
- Environment
- Transport
- Emergency procedure
- Detoxification; responsible disposal

The management of the cyanide user should be open to any safety improvement feedback from the cyanide personnel and also provide regular safety training. An intact pre-emergency concept must be guaranteed, and the functioning of this concept tried out regularly to eliminate any weak points in communication. The most important point is that a medical doctor should be available immediately in the event of an incident.

The cyanide manufacturer must provide the user with the necessary safety information, so that the user can implement safety measures and carry out his own internal safety training and surveys.

It is recommended that the following material is provided to the responsible personnel:

- Pocket cards with instructions for safe handling
- Medical brochures with recommendations for the medical practitioners
- Placards and signs for cyanide areas
- Video with recommendations on safe handling
- Transport Cards for transport personnel

1. Introduction

Many acyclic compounds containing C – N double or triple bonds tend to condense to form six-membered rings with alternating C and N atoms:

These derivatives are called *s*-triazines or 1,3,5-triazines. Although the ring structure is not quite a regular hexagon, spectroscopic data indicate an aromatic character of the ring system [7]. The aromaticity of the triazine ring is discussed in [6, p. 466]. A large number of their reactions are described in the literature, mostly substitution reactions with ring retention.

Compound **1** is commonly called cyanuric acid, even though the oxo (keto) structure **1b** is dominant over the hydroxy (enol) structure **1a**. Reactions with electrophiles generally give derivatives with structure **1b** (isocyanurates, e.g., **1** – **28**). Triazine compounds of structure **1a** (cyanurates, e.g., **30** – **55**) are made from cyanuric chloride (**29**). Compounds of industrial importance of both types are shown in Tables 1 and 2.

Compounds that are mixtures of tautomers are known, although the keto structure is generally more stable than the hydroxy structure. Some alkyl cyanurates rearrange to give the corresponding isocyanurates [1], [8], [9]. The rearrangement of triallyl cyanurate (TAC) (**39**) to triallyl isocyanuarate (TAIC) (**11**), which can be carried out thermally or catalytically is of some industrial interest.

Cyanuric acid and cyanuric chloride are readily interconvertible [10], [11]:

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a08_191

Although cyanuric acid and cyanuric chloride have been known since 1776 and 1827, respectively, they only gained industrial importance in the 1950s.

2. Cyanuric Acid

2.1. Physical Properties

Cyanuric acid [*108-80-5*], isocyanuric acid, 1,3,5-triazine-2,4,6(1*H*,3*H*,5*H*)-trione (**1**), $C_3H_3N_3O_3$, M_r 129.8, *mp* 320–330 °C (decomp.), is an odorless white solid, $d_0^4 = 1.8$. Its solubility in water is 0.2 wt % at 10 °C and 2.6 wt % at 90 °C. At room temperature cyanuric acid is only slightly soluble in common organic solvents such as acetone, benzene, ether, ethanol, hexane, and isopropyl alcohol (0.1 wt %). Cyanuric acid has significant solubility in solvents with large dipole moments. The solubility (wt %) of cyanuric acid at 25 °C is as follows:

Dimethyl sulfoxide	17.4
Sulfuric acid (98 wt %)	14.1
Dimethylformamide	7.2
N-methyl-2-pyrrolidone	6.3
Dimethylacetamide	3.0
Pyridine	2.2

Cyanuric acid crystallizes from water as a colorless crystalline dihydrate, which loses water in dry air. Cyanuric acid is a weak tribasic acid (K_a values ca. 10^{-7}, 10^{-11}, and 10^{-14} [3, D1]). The solubilities of the mono-, di-, and trisodium salts in water are 0.9, 5.7, and 14.1 g per 100 mL of solution, respectively [12]. For other physical data, see [1] and [3, D1].

2.2. Chemical Properties

Only a few reactions of cyanuric acid occur by replacement of hydrogen at oxygen: in alkaline solution the hydroxy structure is favored over the keto structure. Salts are formed with inorganic and organic bases [1].

M = alkali or alkaline earth metal

The reaction of cyanuric acid with ammonia under pressure in the presence of a catalyst at 350–400 °C produces melamine [*108-78-1*] [13], [14], [15].

In the presence of alkaline catalysts, ketene reacts with cyanuric acid to afford triacetyl cyanurate [*13483-16-4*] in high yield [16].

The typical reactions of cyanuric acid are those of a cyclic imide, in which the nucleophilic isocyanurate nitrogen atom, mostly in the form of an anion, attacks a positively polarized carbon atom of the reaction partner. This type of reaction usually results in trisubstitution. Epoxides undergo addition to form hydroxyalkyl isocyanurates when heated in DMF. Ethylene oxide reacts nearly quantitatively at 100 °C to form tris(2-hydroxyethyl) isocyanurate (**8**). Similarly, propylene oxide gives the corresponding hydroxypropyl analogue [17], [18]. Epichlorohydrin forms tris(3-chloro-2-hydroxypropyl) isocyanurate (**9**) in dioxane at 110 °C in the presence of basic catalysts [19]; its dehydrochlorination in aqueous alkali produces the commercial product tris(2,3-epoxypropyl) isocyanurate (**10**) [20]. A typical addition reaction of cyanuric acid to a double bond is the formation of bis(2-cyanoethyl) isocyanurate [*2904-27-0*] and tris(2-cyanoethyl) isocyanurate (**27**) by reaction with acrylonitrile in DMF containing Triton B (a surfactant) at 130 °C [18]. Saponification of tris(2-cyanoethyl) isocyanurate gives tris(2-carboxyethyl) isocyanurate (**22**). Esterification of **22** with ethanol gives tris(2-carbethoxyethyl) isocyanurate (**23**), which is a starting material for the commercial light stabilizer and antioxidant **24**. Cyanuric acid dissolves readily in aqueous formaldehyde [12], [21] with formation of tris(hydroxymethyl)

isocyanurate (**18**). Alkyl halides react with cyanuric acid at elevated temperature in the presence of a proton acceptor with elimination of hydrogen halide. Thus, allyl chloride forms the commercial product triallyl isocyanurate (**11**) in dichlorobenzene/triethylamine at 130 °C [22], [23]; 2-chloroethanol yields tris(2-hydroxyethyl) isocyanurate (**8**) in aqueous sodium hydroxide [24]. The trisubstituted isocyanurates (**11**) – (**17**), (**21**), and (**26**), as well as the commercial products (**19**) and (**20**) can be prepared similarly. Chlorine reacts with cyanuric acid in water at controlled pH to afford the *N,N′*-dichloro and *N,N′,N″*-trichloro compounds (**3**) – (**7**) (→ Chloroamines). Which compound is formed depends upon the ratio of sodium hydroxide to cyanuric acid. If a 2:1 molar ratio is used, mainly *N,N′*-dichloroisocyanuric acid (DCCA) is obtained. If a 3:1 molar ratio is used, mainly *N,N′,N″*-trichloroisocyanuric acid (TCCA) is obtained in 90 % yield.

Cyanuric acid decomposes slowly above 200 °C and rapidly above its melting point (320 – 330 °C). The main product is isocyanic acid [*75-13-8*] [25], [26]. At higher temperature, some reactions are likely to proceed via a cyanic acid intermediate, that is, they involve ring cleavage.

Another example of ring cleavage is the conversion of long-chain fatty acids into nitriles above 250 °C [27].

2.3. Production

Laboratory quantities of pure cyanuric acid are produced by hydrolysis of cyanuric chloride [11] or melamine [28]. The acid is further purified by recrystallization from dimethylformamide or via the sodium or ammonium salts.

On a commercial scale cyanuric acid is manufactured by pyrolysis of urea between 200 and 300 °C to give ammonia and cyanuric acid.

In some processes, urea is heated in a kiln for several hours. The process starts with molten raw material and ends with solid cyanuric acid. Numerous patents deal with methods to improve heat and mass transfer with specially designed reactors or with a modified reaction mixture. The reaction can be carried out in heated screws, revolving drums [29], steel conveyor belts [30], rotary-tube furnaces [31], or ball mills [32]. Pyrolysis in a fluidized bed of AlF_3 particles [33] or cyanuric acid crystals [34] and heating of molten urea by high-frequency induction have also been reported [35]. The caking problem is solved by premixed powders with definite urea to cyanuric acid ratios [31], or preformed urea cyanurate [34], [36], or by recycling the crude product [31]. Other methods use molten metals [37], [38] or salts [39] as the heat-transfer medium. Urea is fed into the bottom of a crucible filled with agitated molten tin or tin alloy, and the cyanuric acid collects at the metal surface. Other methods employ high-boiling solvents such as polyglycol ethers [40] and sulfolanes [41], which dissolve urea but not cyanuric acid. These methods avoid

localized overheating, which reduces yields by formation of isocyanic acid. Other solvents have also been reported [3, D1, p. 369]. Byproduct formation is suppressed by rapidly removing the ammonia at reduced pressure, sparging with inert gas, or codistillation.

Crude cyanuric acid contains up to 30 % impurities, consisting mainly of melamine and its precursors:

Biuret [*108-19-0*]

Triuret [*556-99-0*]

Ammelide [*645-93-2*]

Ammeline [*645-93-1*]

Melamine [*108-78-1*]

Dilute mineral acids convert the impurities to ammonia and carbon dioxide or cyanuric acid [31], [42]. Another method is to dissolve the crude acid in NaOH or dilute aqueous ammonia, to filter the organic impurities off, and to precipitate the acid by adding mineral acids [43], [44].

2.4. Environmental Protection

Cyanuric acid is biodegraded readily under anaerobic conditions [45], in the soil [46], and in aerated systems [47], [48]. The principal environmental impact comes from salt in the effluents resulting from the manufacture of cyanuric acid and its derivatives.

2.5. Quality Specifications and Chemical Analysis

Cyanuric acid is available as solid in powdered form or mainly in coarse granular form, ≥ 85 % 10 – 100 mesh. Manufacturers' specifications are in the following range:

Cyanuric acid	≥ 98.5
Ammelide + ammeline	≤ 1 %
Color (APHA)	≤ 50
Moisture	≤ 0.6 %
Ash	50 – 1000 ppm
pH	4 – 5 (0.25 % solution or 10 % slurry)

Thin-layer chromatography on cellulose is suitable for quality control. Cyanuric acid is determined gravimetrically as its melamine salt [49] or by potentiometric titration of a solution in DMSO/benzene with tetrabutylammonium hydroxide [50], [51]. In wastewater cyanuric acid can be determined by amperometric titration with $Hg(NO_3)_2$ [52] or by differential pulse polarography [53]. Solid cyanuric acid can be readily identified by IR spectroscopy [54] or X-ray diffraction. Cyanuric acid and the isocyanurates can also be determined by nitrogen analysis according Kjeldahl or Dumas. Impurities in cyanuric acid are determined as follows:

- Liberation, distillation, and determination of ammonia (Kjeldahl, Dumas, or ion-selective electrodes [55])
- Determination of urea by urease acidimetry
- Determination of biuret by UV spectrophotometry

2.6. Storage and Transportation

Cyanuric acid should be stored in a dry place. Silos and pneumatic conveyors should be grounded to prevent electrostatic discharges. The loose bulk density is 800 – 900 g/L. The product is packed in polyethylene-lined fiber drums or paper bags. The shipping classification in the United States is "Acid, NOIBN, Dry" (NOIBN, not dangerous according to DOT CFR Title 49).

2.7. Uses

Cyanuric acid is widely used for the manufacture of *N*-chlorinated isocyanurates (**3**) – (**7**), which are employed most importantly in swimming pool disinfectants, household bleaches, industrial and institutional cleaners, dishwasher detergents, and general sanitizers (→ Chloroamines). Cyanuric acid serves as stabilizer of available chlorine in swimming pools. In concentrations of 25 – 50 ppm, it reduces the deactivation rate of chlorine by a factor of 5 – 10 [56]. Cyanuric acid is approved as a source of nitrogen in ruminant feed [57], [58]. The use of cyanuric acid as a source of isocyanic acid by heating to 450 – 650 °C has been claimed [59]. Small quantities of cyanuric acid are used for reducing nitrogen oxides (NO_x) in stationary diesel engine exhaust gas or in coal-, oil-, or gas-fired boilers. The isocyanurates **8** – **12**, **22**, and **23** are used in the plastics industry [12], [60]. Triallyl isocyanurate (TAIC; **11**) can be homopolymerized and copolymerized. It serves as cross-linking agent in polyethylene and poly(vinyl chloride) and in laminate formulations [61], [62]. Tris(2-hydroxyethyl) isocyanurate (THEIC; **8**) is a cross-linking agent for polyurethanes, polyesters, and alkyd resins used for wire enamels and electrical varnishes [63]. Triglycidyl isocyanurate (TGIC; **10**) is a cross-linking agent in epoxy resins [19], [64] and a curing agent for weather-resistant powder coatings. Melamin cyanurate (**28**) has achieved commercial importance as halogen-free flame retardant in polyamide resins and compositions [65]. It is also useful as a solid lubricant [66]. Tris(2-carboxyethyl) isocyanurate (TCEIC; **22**) is used in making water-soluble alkyd resins; the esters serve as plasticizers for poly(vinyl chloride) and lubricants [67], [68]. An overview of important products based on cyanuric acid is given in Table 1.

2.8. Economic Aspects

World capacity for cyanuric acid is estimated to be 80 000 t/a (1997), more than 90 % of which is used to make *N*-chlorinated isocyanurates. Monsanto, FMC and Olin (all USA) are the world's largest bulk suppliers of cyanuric acid and chlorinated isocyanurates. In Dezember 1992 Occidental Chemical entered the US market by purchasing Monsanto's ACL business (chlorinated isocyanurates). The plants will continue to be operated by Monsanto. Important producers of cyanuric acid are listed in the following:

United States	FMC, Monsanto, Occidental, Olin
Japan	Shikoku Kasei Kogyo, Nissan Chemical Industries, Nippon Soda
France	Atochem
Spain	Delsa
Italy	Sigma
Germany	BASF
Taiwan	Ferrel Int., Kuang Ming Enterprise, Tai-Yu Chem. Ind.

There are also smaller producers in China, Korea and the former Soviet Union. All major producers also make the chlorinated derivatives.

2.9. Toxicology and Occupational Health

Cyanuric acid has been classified as essentially nontoxic (acute oral and dermal), nonirritating to the skin, and essentially nonirritating to the eye [12], [69].

Acute toxicity	
LD_{50} (rat, oral)	> 5000 mg/kg [70]
LD_{50} (rabbit, dermal)	> 5000 mg/kg
LC_{50} (fish)	> 2000 mg/L (24h) [71]
EC_{50} (Daphnia)	> 2000 mg/L [71]
Subacute toxicity	
NOEL (fish)	1000 mg/L [71]
NOEL (algae)	2500 mg/L [71]
Inhib. of reprod. (Daphnia)	1000 mg/L [71]

Inhalation of the dust, contact with the eye, and ingestion should be avoided. Above 200 °C, cyanuric acid forms toxic isocyanic acid.

3. Cyanuric Chloride

3.1. Physical Properties

Cyanuric chloride, 2,4,6-trichloro-1,3,5-triazine [*108-77-0*] (**29**), $C_3N_3Cl_3$, M_r 184.5, triple point 145.7 °C at 255 kPa; *bp* 194 °C, d_4^{20} 1.92 (solid), d_4^{150} 1.48 (melt), forms colorless monoclinic crystals of pungent odor, reminiscent of acetamide and acid chlorides. The compound is soluble in acetonitrile, ether, ketones, and chlorinated hydrocarbons, but insoluble in water. The

Figure 1. Vapor pressure of liquid cyanuric chloride

solubility (in wt %) of cyanuric chloride in various solvents at 25 °C is as follows:

Acetone	25.0
Acetonitrile	21.0
Acrylonitrile	19.0
Benzene	19.0
Chlorobenzene	16.0
Tetrachloromethane	7.5
Diethyl ether	14.0
Dioxane	55.0
Ethyl acetate	21.0
Methyl vinyl ketone	27.0
Nitrobenzene	18.0
Tetrahydrofuran	43.0
Trichloromethane	20.0

The solubility in toluene at various temperatures is as follows:

at 20 °C	17.2 wt %
at 30 °C	19.8 wt %
at 40 °C	25.0 wt %
at 50 °C	29.7 wt %

Heat capacity c_p is $0.99\,\mathrm{kJ\,kg^{-1}\,K^{-1}}$ at 150 °C, heat of fusion is 123 kJ/kg, and heat of vaporization is 256 kJ/kg. The vapor pressure of cyanuric chloride as a function of temperature is shown in Figure 1.

The vapor pressure (kPa) of the liquid as a function of temperature (°C) is given by

$$\ln p/\mathrm{mmHg} = -0.33480 - 742.7311/(T/\mathrm{K}) + 11.15147 \ln (T/\mathrm{K})$$

Cyanuric chloride sublimes before reaching the boiling point; the vapor pressure (in mbar) of the solid is:

At 20 °C	0.025
At 62 °C	1.040
At 70 °C	2.700
At 114 °C	34.900

3.2. Chemical Properties

Under anhydrous conditions, cyanuric chloride can act as a chlorinating agent. Alcohols and tertiary amines are converted to alkyl chlorides [72], [73]. Carboxylic acids form acid chlorides in anhydrous acetone in the presence of triethylamine. The acid chloride can be isolated or treated in situ to give the ester, amide, etc. [74]. In both cases cyanuric acid is formed as byproduct.

Cyanuric chloride can be used as a condensation (water-withdrawing) reagent in chemical synthesis. Amides and thioamides can be converted to nitriles.

Table 2. Cyanuric acid as condensation/halogenation/oxidation agent in organic synthesis [74–85]

Starting material	Product	Refs.
$RCONH_2$ Carboxylic acid amides	RCN Carboxylic acid nitriles	[75], [76]
Aldoximes	R-CN Carboxylic acid nitriles	[75]
 Ethers	 Carboxylic esters	[77]
Carboxylic acids	 Carboxylic acid esters	[78]
Hydroxycarboxylic acids	Cyclic esters (lactones)	[79]
Maleic acid derivatives	 Maleimide	[80]
RCOOH Carboxylic acids	$RCONH_2$ Carboxylic acid amides (peptides)	[74]
 X = O, N, S	 Carbodiimides	[81], [82]
Substituted thioureas		
ROH Alcohols	RY Y = Cl, Br Alkyl halides	[83], [84] [85]
RCOOH Carboxylic acids	RCOCl Carboxylic acid chlorides	[74]

Aldoximes react in an analogous way. A selection of important reactions in which cyanuric chloride acts as chlorination/condensation reagent are listed in Table 2.

Under anhydrous conditions tertiary aliphatic amines are converted to substituted melamine derivatives. At the same time one alkyl group is removed and converted to the corresponding alkyl chloride [73].

Cyanuric chloride usually reacts like an acid chloride with formation of hydrogen chloride.

According to Fierz – David [86] a suspension of cyanuric chloride in ice water (0 °C) is fairly stable for nearly 12 h. Above 10 °C hydrolysis occurs rapidly; for example, at 30 °C more than 40 % of the cyanuric chloride is hydrolyzed within 1 h. The final hydrolysis product is cyanuric acid. Figure 2 shows the dependence of the hydrolysis of cyanuric chloride ($c = 50$ g/L) in water as a function of hydrolysis time at different temperatures.

Figure 2. Hydrolysis of cyanuric chloride as a function of temperature

In an alkaline aqueous medium, e.g., in the presence of NaOH or $NaHCO_3$, at 40 °C, 2,4-dichloro-6-hydroxy-1,3,5-triazine is formed. With an excess of base 2,4-dihydroxy-6-chloro-1,3,5-triazine is formed. Trisodium cyanurate is formed only above 125 °C. A number of processes take advantage of the temporary stability of cyanuric chloride in water by reacting a suspension of finely divided cyanuric chloride in ice water with a strong nucleophilic agent such as an alcohol, a thiol, or a primary or secondary amine [87]. These reactions often proceed stepwise to trisubstitution at a well-defined temperature. An empirical rule for amine substituents states that the first chlorine substituent is replaced at 0 – 5 °C, the second at 30 – 50 °C, and the third at 70 – 100 °C [86]. Sodium hydroxide, sodium hydrogencarbonate, disodium hydrogenphosphate, and tertiary amines can be used as HCl scavengers (see also [6, p. 483]).

The triazine product is usually isolated by filtration or centrifugation. Solvents such as acetone, methyl ethyl ketone, or toluene are often used for these reactions. Cyanuric chloride, melt or powder, is dissolved or suspended in the solvent with the nucleophile and treated with aqueous NaOH. The product is filtered or is isolated from the organic layer by evaporation. Both methods are used to introduce different substituents successively at different temperatures. Replacement of the third chlorine atom is sometimes carried out by employing high-boiling solvents or simply the molten reactant. Care must be taken to neutralize the liberated hydrochloric acid and to dissipate the heat of reaction. Otherwise, the exothermal hydrolysis of cyanuric chloride ($\Delta H = -2164$ kJ/kg) can become uncontrollable, especially in the manufacture of cyanurates from alcohols [88]. Hydrolysis is accelerated by water-miscible solvents. Storage of solutions of cyanuric chloride in aqueous acetone without heat removal can result in a runaway reaction, which can even start at room temperature. Cyanuric chloride reacts with DMF to form Gold's salt [*20353-93-9*] [89].

$$3\left[(CH_3)_2N{=}CH{-}N{=}CH{-}N(CH_3)_2\right]^+ Cl^- + 3\,CO_2$$

The reactions of cyanuric chloride are surveyed in [90], [91].

3.3. Production

Most cyanuric chloride facilities are found at plants producing hydrocyanic acid, the key starting material. Sodium cyanide is a minor source.

The *hydrocyanic acid* is chlorinated to cyanogen chloride, which is trimerized directly to cyanuric chloride:

$$HCN + Cl_2 \longrightarrow ClCN + HCl \quad \Delta H = -89\ \text{kJ/mol}$$

$$3\,ClCN\ (g) \longrightarrow (ClCN)_3\ (g) \quad \Delta H = -233\ \text{kJ/mol}$$

In a typical process, hydrocyanic acid and chlorine are fed to a loop reactor at 20 – 40 °C (see Fig. 3). Cyanogen chloride saturates the aqueous reaction medium and leaves the loop (a and b) [92]. It is washed with water (c) and dried (d) and is then ready for trimerization.

The wash water from c dissolves the hydrogen chloride and delivers it to a stripper (e), which recycles dissolved cyanogen chloride and releases hydrochloric acid. Sections e, a, and c can also be combined in a single apparatus [93].

The dry cyanogen chloride is trimerized at ≥ 300 °C on activated carbon (f) [94], [95]. The cyanuric chloride vapors are condensed to molten or solid product (g) [96], [97], which is dissolved in a solvent for captive use or filled from a hopper (h) into containers (i). Tail gases are scrubbed and recycled (k).

The ClCN yield in this process exceeds 95 %; the $(ClCN)_3$ yield exceeds 90 %.

A number of processes eliminate the formation of dilute hydrochloric acid during cyanogen chloride manufacture: a one-step gas-phase reaction of hydrocyanic acid and chlorine on charcoal [98], [99] or in tetrachloroethane [100], and a one-step reaction of cyanogen and chlorine on charcoal [101].

Figure 3. Production of cyanuric chloride from chlorine and hydrocyanic acid
a) ClCN reactor; b) Heat exchanger; c) Scrubber; d) Dryer; e) Effluent stripper; f) Trimerizer; g) Condenser; h) Storage; i) Drum; k) Tail gas scrubber

Catalysts for cyanogen chloride trimerization other than activated carbon include fused cyanuric chloride [102], [103], molten aluminum chloride [104], eutectic mixtures of tetrachloroaluminates [105], aluminum silicates [106], and zeolites [107] doped with metal oxides or sulfides [108].

In some of these processes, "tetrameric cyanogen chloride" (2,4-dichloro-6-isocyanodichloro-5-triazine) [*877-83-8*] is a byproduct; its conversion into cyanuric chloride is catalyzed by iron oxide [109], [110].

In the laboratory, ClCN in benzene or chloroform solution trimerizes in the presence of hydrogen chloride [111]. The use of the hydrogen chloride – dimethyl ether azeotrope on a commercial scale has been patented [112].

Equipment for cyanogen chloride production is lined with glass or fluoro polymers, or made of graphite or special resins. For cyanuric chloride, nickel, stainless steels, or aluminum is used. Moisture causes severe corrosion.

3.4. Environmental Protection

Normally the only effluent is dilute hydrochloric acid from cyanogen chloride production. This acid is usually kept below the concentration of the H_2O – HCl azeotrope, since the unwanted hydrolysis of ClCN depends on the concentration of the acid. Uses for this weak acid are very limited; appreciable amounts are neutralized with caustic soda or limestone, or in ion exchangers.

Residual gases from the trimerization are washed or condensed to recycle excess chlorine and unreacted ClCN. The tail gases consist of nitrogen and carbon dioxide; when they contain chlorine, they can be used to make bleach (NaOCl).

Spilled molten cyanuric chloride is cooled by covering it with foam to prevent sublimation. The solid is collected and hydrolyzed to cyanuric acid. Fumes from venting of tanks containing molten cyanuric chloride are scrubbed with the anhydrous solvent used in the consumer's process.

3.5. Quality Specifications and Analysis

The industrial product contains 99 % cyanuric chloride (min.) and less than 1 % insolubles. In many applications, cyanuric chloride is in suspension, so particle size is important. To facilitate reaction and avoid dust formation, a particle size between 10 and 160 µm (> 80 mesh Tyler) is optimal. Different sieving methods give different results because of abrasion or agglomeration.

To test reactivity, cyanuric chloride and an amine are reacted under standard conditions and the unchanged material is determined.

Hydrolysis caused by improper handling may result in contamination with cyanuric acid, which is found as insoluble matter in dried solvents such as toluene.

Cyanuric chloride can be assayed via the melamine complex by IR spectroscopy after hydrolysis of a chloroform extract [113], or by titration of excess reagent after reaction with morpholine [114].

3.6. Storage and Transportation

The solid is shipped in drums, with or without polyethylene liners, or in bulk bins. Free-flowing

cyanuric chloride is also transported in fluidized bulk trailers; molten product is shipped in heated tank trailers.

Cyanuric chloride should be stored in strictly dry conditions. The solid should be stored in a cool place to avoid an increase in particle size. Tank farms for molten product must have a well-designed heat-tracing system that includes the vent and relief lines.

The following transportation regulations apply:

Road (GGVS/ADR)	Class 8, 39b
Rail (GGVE/RID)	Class 8, 39b
Sea (IMDG)	Class 8; UN no. 2670, PG II
Air* (ICAO-TI/IATA/-DGR)	Class 8; UN no. 2670, PG II

* Only for small samples.

3.7. Uses

The most important cyanuric chloride derivatives are the aminotriazines. Alkylaminotriazines are used as pesticides and herbicides (**40**–**42**). The triazines are still among the largest selling herbicides; most of them are 2-chloro- or 2-methylthio-4,6-dialkylamino-1,3,5-triazines. Simazine (**42**) is one of the oldest. The most important triazine-based herbicide is atrazine (**40**).

Reaction products of aminostilbenes with substituted triazines are used as brightening agents for fabrics and paper (→ Optical Brighteners), especially bis(triazinylamino)stilbenedisulfonic acids (**43**).

Dye derivatives prepared from cyanuric chloride react chemically with fabrics (→ Reactive Dyes). The Procion dyes (**45**) were among the first.

Cyanuric chloride (**29**) and cyanurates are used as cross-linking agents. Cyanuric chloride (**29**) and especially 2,4-dichloro-6-hydroxy-1,3,5-triazine (**30**) and 2,4-dihydroxy-6-chloro-1,3,5-triazine (**31**), both in the form of their sodium salts, are used in gelatin and glues [115]; triallyl cyanurate (**39**) is used in the rubber and plastic industry (→ Allyl Compounds, Chap. 3.3.1.) [116]. Other uses of triazines include modifiers, accelerators, UV stabilizers, flame retardants, pharmaceuticals, antioxidants, antiozonants, and heavy metal scavengers.

An overview of important products based on cyanuric chloride is given in Table 3. The important class of triazine-based herbicides is surveyed in [117].

3.8. Economic Aspects

Worldwide annual production of cyanuric chloride exceeds 100 000 t/a. The available capacities are well above demand. Producers are listed in Table 4. The capacity of production units ranges from hundreds to several thousand tonnes per month.

Table 4. Manufacturers of cyanuric chloride

Country	Company
Belgium	Degussa
Federal Republic of Germany	Degussa
	SKW-Trostberg
Former Soviet Union *	
Switzerland	Lonza
United States	Novartis *
	Degussa

* Captive use only.

More than 70 % of production is used for pesticides and especially herbicides, with about 70 % of that volume for atrazine (**40**). Triazine herbicides are produced all over the world. Less than 30 % of demand is accounted for by industrial applications, predominantly optical brighteners, UV stabilizers, reactive dyes, and certain anthraquinone dyes. Applications based on cross-linking chemicals such as triallyl cyanurate (**39**) are of increasing importance.

3.9. Toxicology and Occupational Health

Cyanuric chloride strongly irritates the skin, mucous membranes, including those of the eye, and the respiratory and gastrointestinal tracts [70, pp. 2763–2765]. The 1-min irritation threshold for the mucous membranes is 0.3 mg/m^3. Allergic reactions are possible.

Direct contact with cyanuric chloride should be avoided; ventilation in the work place is necessary. A full-face gas mask with an active-carbon canister or a self-contained breathing apparatus must be used during exposure to vapor and dust. Cyanuric chloride is labeled with the hazard symbol X_i and assigned to the groups R

Table 3. Selected triazine derivatives based on cyanuric chloride

Compound (abbreviation)	Application	CAS registry no.	Structure	Number
Cyanuric chloride (CC)	starting material for herbicides, optical brighteners, reactive dyes, cross-linking agents	[*108-77-0*]		**29**
2,4-Dichloro-6-hydoxy-1,3,5-triazine sodium salt	cross-linking agent for gelatin	[*2736-18-7*]		**30**
2,4-Dihydroxy-6-chloro-1,3,5-triazine disodium salt	cross-linking agent for gelatin	[*67410-55-3*]		**31**
2,4-Dichloro-6-methoxy-1,3,5-triazine	pesticide intermediate	[*3638-04-8*]		**32**
2-Chloro-4,6-dimethoxy-1,3,5-triazine	intermediate for UV-stabilizers and optical brighteners	[*3140-73-6*]		**33**
2-Methylthio-4,6-dichloro-1,3,5-triazine	pesticide intermediate	[*13705-05-0*]		**34**
2-Amino-4,6-dichloro-1,3,5-triazine	gelatin hardener for photographic paper	[*933-20-0*]		**35**
4,6-Dichloro-2-(2'-chloroanilino)-1,3,5-triazine	nonsystemic foliar fungicide with protective action	[*101-05-3*]		**36**

Table 3. (Continued)

Compound (abbreviation)	Application	CAS registry no.	Structure	Number
2-Chloro-4,6-diamino-1,3,5-triazine	adhesion promoter for rubber and metal composites	[*3397-62-4*]		**37**
2,4,6-Tris(hydroxy-ethylamino)-1,3,5-triazine (THEM)	modifier for melamine resins	[*4403-07-0*]		**38**
Triallyl cyanurate (TAC)	cross-linking agent	[*101-37-1*]		**39**
2-Chloro-4-(ethylamino)-6-(isopropylamino) triazine	herbicide	[*1912-24-9*]		**40**
2-[[4-chloro-6-(ethylamino)-*s*-triazin-2-yl]amino]-2-methylpropionitrile	herbicide	[*21725-46-2*]		**41**
Chlorobis(ethylamino)triazine	herbicide	[*122-34-9*]		**42**
Bis(triazinylamino)stilbensulfonic acids	optical brighteners			**43**

Table 3. (Continued)

Compound (abbreviation)	Application	CAS registry no.	Structure	Number
2,4-Dimethoxy-6-(1-pyrenyl)-1,3,5-triazine	optical brightener for polyester fibers	[*3271-22-5*]		**44**
Procion Brilliant Orange M-G	reactive dye	[*6522-74-3*]		**45**
2,4,6-Trismercapto-1,3,5-triazine sodium salt (TMT)	heavy metal scavenger	[*17766-26-6*]		**46**
2,4-Diamino-6-(cyclopropylamino)-1,3,5-triazine	insect growth regulator for leaf miner control	[*66215-27-8*]		**47**
2,4,6-Tris(1-aziridinyl)-1,3,5-triazine	cross-linking agent; thermal-transfer printing materials	[*51-18-3*]		**48**
2,4,6-Tris-(dimethylamino)-1,3,5-triazine	antitumor agent	[*645-05-6*]		**49**

36/37/38; S 28. The following R and S phrases should also be applied:

R 22	harmful if swallowed
R 26	very toxic by inhalation
R 41/43	may cause sensitization by inhalation and skin contact
S 36/37/39	wear suitable protective clothing, gloves and eye/face protection
S 45	in case of accident or if you feel unwell, seek medical advice immediately

Funnels for adding cyanuric chloride powder to flammable solvents must be grounded. Cyanuric chloride should only be handled by qualified personnel.

1. Cyclododecanol and Cyclododecanone

Commercial production of cyclododecanol [*1724-39-6*] (**3**) and cyclododecanone [*830-13-7*] (**4**) began when WILKE et al. [1], [2] found an efficient synthesis for 1,5,9-cyclododecatriene [*4904-61-4*] (**1**)by cyclotrimerization of butadiene [*106-99-0*]. First made byDuPont in the United States and Hüls in Europe, world production capacityhas since risen to ca. 5×10^4 t/a. Cyclododecanol and cyclododecanone are mainly used to synthesize dodecanedioic acid [*693-23-2*] (**5**) and azacyclotridecane-2-one [*947-04-6*] (laurolactam, **8**).

1.1. Properties

At room temperature, both cyclododecanol, $C_{12}H_{24}O$, and cyclododecanone, $C_{12}H_{22}O$, are colorless crystals that are soluble in organic solvents but only slightly soluble in water (0.004 wt % at 298 K). Table 1 lists further physical properties for both.

Cyclododecanol reacts like an aliphatic secondary alcohol. Dehydration of cyclododecanol in dilute sulfuric acid or in the gas phase with catalysts yields cyclododecene [*1501-82-2*]. When treated with organic acids or anhydrides, cyclododecanol forms esters. Oxidation of cyclododecanol with nitric acid gives dodecanedioic acid (**5**). Dehydrogenation of cyclododecanol at about 230 °C yields cyclododecanone, and hydrogenation of cyclododecanol produces cyclododecane [*294-62-2*] (**2**).

In most cases, cyclododecanone reacts like an aliphatic ketone [3]. Hydroxylamine converts cyclododecanone into cyclododecanone oxime [*9466-89-4*] (**7**), Beckmann rearrangement of which yields laurolactam (**8**). Addition of hydrocyanic acid to cyclododecanone produces cyanohydrin (95 % yield) [4]. Treatment of cyclododecanone with elemental bromine yields 2-bromocyclododecanone and 2,11-dibromocyclododecanone [5], which are used as precursors for fragrances and musks.[6] Aldol condensation [7] and Wittig reaction [8] are also known for cyclododecanone.

Although cyclododecanone gives pure cyclododecanol when hydrogenated under pressure in the presence of a copper – chromium cat-

alyst, more severe conditions produce cyclododecane. Upon oxidation with nitric acid, cyclododecanone, like cyclododecanol, yields dodecanedioic acid; however, the oxidation of cyclododecanol is more efficient.

1.2. Production

Cyclododecane (**2**), which is obtained by catalytic hydrogenation of 1,5,9-cyclododecatriene (**1**; → Cyclododecatriene, Cyclooctadiene, and 4-Vinylcyclohexene), is the starting material for producing cyclododecanol and cyclododecanone.

Oxidation of cyclododecane with air or oxygen gives cyclododecanol and cyclododecanone [9]. The standard enthalpies of reaction are − 205 and − 395 kJ/mol, respectively. Cyclododecane hydroperoxide [*2698-67-1*] is involved in the oxidation as intermediate, but in general it is decomposed directly by a catalyst. Boric acid has found broad industrial application as catalyst [10–13].

Continuous or batch air oxidation (boric acid catalyst, atmospheric pressure, 160 – 180 °C) converts 25 – 30 % of the cyclododecane. Because boric acid esterifies the cyclododecanol product, the reaction mixture (cyclododecane, cyclododecyl borate, cyclododecanone) is treated with water and alkali at 90 – 100°C to hydrolyse the ester. After separation of the aqueous and organic phases, cyclododecane is distilled from the organic phase under reduced pressure and recycled for further oxidation. The aqueous phase is concentrated, and boric acid can be crystallized as orthoboric acid, dried, and also returned to the oxidation section. The selectivity of the overall reaction producing a mixture of cyclododecanol and cyclododecanone from cyclododecane is 80 – 82 mol % with a molar ratio of 10/1 (alcohol/ketone).

Pure cyclododecanol is made by hydrogenating the mixture in the presence of a copper – chromium catalyst at 30 MPa and 160°C. Pure cyclododecanone is obtained by dehydrogenating the mixture over copper or copper – chromium catalysts on an active support at 230 – 245 °C and atmospheric pressure [19].

After dehydrogenation (endothermic, 75.4 kJ/mol) the reaction mixture is distilled to give pure cyclododecanone, cyclododecanol, and a small amount of residue.

Figure 1 shows a flow diagram for the process.

Figure 1. Process flow diagram for the production of cyclododecanol, cyclododecanone, and laurolactam (Hüls process) CDAN = cyclodecane, CDOL = cyclododecanol; CDON = cyclododecanone, LL = laurolactam

Storage and Transportation. Cyclododecanol and cyclododecanone are preferably stored and transported in stainless steel containers under a dry inert atmosphere. To prevent crystallisation, vessels or tanks must be heated.

Analysis. Although the melting point generally indicates the purity of cyclododecanone, gas chromatography is the best method for evaluating the purity of cyclododecanone or cyclododecanol.

1.3. Uses

The cyclododecanonol – cyclododecanone mixture from boric acid catalyzed oxidation is the starting material for dodecanedioic acid (**5**) which is used to prepare polyamides like polyamide 612, copolyamides, polyesters, and esters. More recently, dodecanedioic acid has found broad application in coatings [15–17]. Pure cyclododecanone is starting material for the production of laurolactam (**8**). Cyclododecanone and cyclododecanol are intermediates in organic syntheses. The esters and ethers of cyclododecanol are used in fragrances.

2. Laurolactam

Made by Degussa-Hüls, Ems-Ube, and Elf-Atochem, production capacity of azacyclotridecan-2-one [*947-04-6*] (laurolactam, **8**) is about 4×10^4 t/a.Laurolactam is mainly used as monomer in engineering plastics like polyamide 12 and copolyamides.

2.1. Properties

At room temperature, laurolactam, $C_{12}H_{23}NO$ forms colorless crystals that are soluble in organic solvents but only slightly soluble in water (0.03 wt % at 20 °C). Table 1 lists the physical properties of laurolactam.

2.2. Production

There are two main routes for commercial production of laurolactam. Degussa-Hüls and Ems-Ube use cyclododecanone (**4**) as starting material. Ammoximation of pure cyclododecanone with hydroxylammonium sulfate provides cyclododecanone oxime [*946-89-4*] (**7**), which undergoes Beckmann rearrangement in the presence of strongmineral acids at elevated temperatures (115 °C). Figure 1 shows a process flow diagram [18].

Because the oxime melts at 135 °C but begins to decompose at 110 °C, the cyclododecanone (purity 99 %), which is dissolved in a hydrocarbon like hydrocumene, is treated at 90 – 100 °C with an aqueous solution of hydroxylamine sulfate. After removal of the organic phase, the oxime is extracted from the organic phase with cold concentrated sulfuric acid.

Heating the acid solution of the oxime to 100 – 120 °C produces laurolactam. The enthalpy of the reaction (cyclododecanone oxime → laurolactam) is 166 kJ/mol. Water is added, and the crude lactam is extracted into an organic solvent, which is distilled to give the pure laurolactam (95 % yield).

Elf Atochem (France) starts from cyclododecane (**2**) and nitrosyl chloride. In a photoreaction, a nitrosyl radical substitutes a hydrogen atom of cyclododecane to give the unstable nitrosylcyclododecane (**6**), which undergoes tautomeric transformation into cyclododecanone oxime (**7**). Beckmann rearrangement follows, as described above [14].

Storage and Transportation. Laurolactam is stored and transported in molten form in pipelines or stainless steel containers under a dry inert atmosphere. To prevent crystallization containers must be heated. Crystalline laurolactam is handled as powder or granulate in bags.

Analysis. The melting point generally indicates the purity of laurolactam. Gas chromatography is used for further evaluation.

2.3. Uses

Polymerization of laurolactam provides polyamide 12. Hydrolytic polymerization of laurolactam has found broad industrial application, though activated cationic and anionic polymerisation are also well known.

3. Toxicology

The oral LD_{50} of both cyclododecanol and cyclododecanone for rats is > 2.5 g/kg. Contact of cyclododecanol with the skin, eyes, or mucous membranes causes no irritation. Although cyclododecanone has no effect on the eyes or mucous membranes, it does irritate the skin slightly [20].

The oral LD_{50} of laurolactam for rats is 2.33 g/kg; laurolactam does not irritate the skin or mucous membranes.

1. Cyclododecatriene

Commercial production of 1,5,9-cyclododecatriene [*4904-61-4*]began when WILKE et al. [1], [2] found an efficient synthesis by cyclotrimerization of butadiene [*106-99-0*]. Since the first plants were brought onstream by Hüls in 1965 and by DuPont in 1969, world production capacityof cyclododecatriene has risen to 10^5 t/a. Today the main producers of cyclododecatriene are Degussa-Hüls and Shell Chemical in Europe, Du Pont in the United States, and Mitsubishi Chemicals in Asia.

1.1. Properties

While the all-*trans* isomer of 1,5,9-cyclododecatriene melts at 34 °C, the other three isomers have melting points below room temperature. Melting points of technical mixtures depend on the catalyst used and the ratio of isomers that it provides. Further physical properties of the four isomers of 1,5,9-cyclododecatriene, $C_{12}H_{18}$, M_r 108.18, and their reduction products are listed in Table 1. All isomers are colorless and have a typical terpene-like odor.

trans,trans,trans-

cis,trans,trans-

cis,cis,trans-

cis,cis,cis–

1,5,9-Cyclododecatriene

The two main isomers, *cis,trans,trans-* and all-*trans*-1,5,9-cyclododecatriene have been studied extensively [3]. They are generally characterized by their tendency to form complexes with transition metals and to undergo transannular reactions and isomerization.

All isomers behave like typical olefins. Complete bromination forms hexabromocyclododecane [*3194-55-6*]. Selective hydrogenation of cyclododecatriene provides cyclododecene [*1501-82-2*], the remaining double bonds of which exhibit a decline in reactivity . This declining reactivity also leads to good yields of many classical double bond reactions, such as epoxidation, nitrosation [4], hydrocarboxylation, and carbonylation [5]. At higher temperature and pressure complete hydrogenation takes place to yield cyclododecane [*294-62-2*].

1.2. Production; Storage and Transportation; Analysis

1,5,9-Cyclododecatriene is produced by the cyclotrimerization of butadiene in the presence of catalysts based on titanium, chromium, or nickel [6]. The catalysts are prepared by reducing an appropriate salt in a hydrocarbon solvent with an aluminum alkyl. Titanium catalysts [7] produce predominantly the *cis, trans,trans* isomer, whereas nickel and chromium catalysts provide the all-*trans* isomer. In general, the yield of cyclododecatriene is greater than 80 % with some dimerization byproducts and butadiene oligomers. Before distillation of the reaction

cis-Cyclooctene	[*931-87-3*]	43	145	−12	0.847	1.476
Cyclooctane	[*292-64-8*]	48	151	+14	0.835	1.459
4-Vinylcyclohexene	[*100-40-3*]		129	−101	0.831	

product, the catalyst must be deactivated, generally by an aqueous caustic wash.

All isomers of cyclododecatriene and their hydrogenation products are preferably stored in tanks and transported in pipelines or stainless steel or aluminum containers as a liquid. If the all-*trans* product is a major isomer, tanks, pipelines and containers must be heated slightly. Generally, the unsaturated compounds are covered with an inert gas to avoid oxidation reactions, and should contain an inhibitor unless they are to be processed immediately.

Gas chromatography is the best method for evaluating the purity of cyclododecatriene and side products.

1.3. Uses

Cyclododecatriene is an important precursor in organic chemistry. Bromination provides hexabromocyclododecane, which has found industrial application as a flame retardant [8]. Hydrogenation of cyclododecatriene is the most significant reaction, providing cyclododecane as an important intermediate in the synthesis of laurolactam [*947-04-6*], 12-aminododecanoicacid [*693-23-2*], and dodecanedioic acid [*693-23-2*]. These are important monomers for nylon 12, nylon 612, copolyamides [9], polyesters, and coating applications [10].

2. Cyclooctadiene and 4-Vinylcyclohexene

Cyclodimerization of 1,3-butadiene provides 1,5-cyclooctadiene and 4-vinylcyclohex-1-ene as main products. Reaction process and kinetics were examined intensively by WILKE et al. [11] in the late 1960s, but it was only ten years later that commercial production started. World capacity of butadiene cyclodimerization products is estimated at ca. 10 000 t/a, mainly produced by Degussa-Hüls and Shell.

2.1. Properties

1,5-Cyclooctadiene [*111-78-4*] and 4-vinylcyclohexene [*100-40-3*], both C_8H_{12}, M_r 108.18 are colorless liquids with specific odors. Physical properties are listed in Table 1.

cis,cis-1,5-Cyclooctadiene

4-Vinylcyclohexene

Cyclooctadiene and 4-vinylcyclohexene both react like typical olefins. Complete halogenation provides tetrahalogenated compounds. Due to declining double bond activity, selective hydrogenation of cyclooctadiene leads to cyclooctene [*931-88-4*]. At high temperature and pressure hydrogenation provides cyclooctane [*292-64-8*].

Hydrogenation of vinylcyclohexene causes disproportionation to give a mixture of ethylcyclohexane [*1678-91-7*] and ethylbenzene [*100-41-4*] [12]. Dehydrogenation of vinylcyclohexene provides styrene [*100-42-5*] [13].

Further typical olefin reactions such as epoxidation, hydrocarboxylation, and carbonylation are known for both compounds.

2.2. Production; Storage and Transportation; Analysis

When nickel catalysts are modified with appropriate ligands, preferably organophosphorus compounds, cyclodimerization of butadiene takes place instead of cyclotrimerization, and the stable *cis, cis* isomer of cyclooctadiene is obtained in more than 90 % yield with 4-vinylcyclohexene and cyclododecatriene as byproducts. Generally the reaction takes place at about 80 °C and 1 – 5 bar, though higher pressure and temperature are also used. The products are separated and purified by distillation.

When iron complexes [14], [15] or copper catalysts [16] are used instead of nickel, 4-vinylcyclohexene becomes the main dimerization product, which provides a benzene-free route to styrene [17].

Butadiene dimerization products are preferably stored and transported in stainless steel or aluminum containers in a dry, inert atmosphere.

Refractive index and gas chromatography are good methods for evaluating the purity of butadiene dimerization products.

2.3. Uses

Ring opening polymerization of cyclooctene, obtained by the selective hydrogenation of cyclooctadiene, is the most significant industrial application. The macrocyclic polymer, *trans*-polyoctenamer (trade name Vestenamer) with a molecular mass of up to 100 000 is used as modifier in rubbers and thermoplastics.

Small amounts of the monomer are used as a precursors in organic synthesis of fragrances, pharmaceuticals, etc. Halogenated cyclooctadienes and vinylcyclohexenes have found application as flame retardants.

3. Toxicology

Contact with cyclododecatrienes, cyclooctadiene, and vinylcyclohexene slightly irritates the skin. Oral LD_{50} values (rat) follow: cyclooctadiene 1.9 g/kg, 4-vinylcyclohexene 4.55 g/kg, cyclododecatriene 4.4 g/kg. Due to the tendency to form epoxides, the cycloolefins are suspected of causing cancer, especially vinylcyclohexene. Therefore, in 1997 vinylcyclohexene was classified in Category III A2 [18].

1. Introduction

Cyclohexane [*110-82-7*], C_6H_{12}, is a cycloalkane, which was synthesized by Baeyer in1893 and discovered in Caucasian crude oil by Markovnikov soon afterward. Its presence in U.S. crude oils was reported in 1931 [1]. Cyclohexane was first synthesized by hydrogenation of benzene in 1898 [2]. The predominant use of cyclohexane is in the manufacture of nylon.

2. Physical Properties

Like all cycloalkanes and related cycloolefins, cyclohexane is a clear liquid with a pungent petroleum-like odor. It is essentially insoluble in water but miscible in most organic liquids, and is noncorrosive, easily flammable, and considered to be much less toxic than benzene.

Cyclohexane can exist in two conformations, the chair and boat forms:

Transformation from one isomer to the other involves rotation about carbon – carbon single bonds. The energy barriers associated with the transformation are low, but the boat form is estimated to have a potential energy 21 – 25 kJ/mol higher than the chair form [3]. As a result, cyclohexane is almost exclusively in the chair form at room temperature. Stereochemistry has no influence on its use as a raw material for nylon manufacture or in other applications.

Table 1 lists the important physical properties of cyclohexane; two closely related naphthenes, methylcyclopentane and methylcyclohexane; and the olefinic homologue, cyclohexene. Table 2 compares the key properties of some alkylcyclohexanes with cyclohexane. Tables 3, 4, and 5 give boiling points and compositions for azeotropes of cyclohexane with various compounds.

Although cyclohexane does not ignite spontaneously at ambient temperature, it must be kept away from an open flame. Information on the explosive limits and ignition properties for cyclohexane and related compounds is given in Table 6.

3. Chemical Properties

Cyclohexane is a relatively stable, nonpolar ring compound. Therefore, with thermal treatment, little isomerization to methylcyclopentane or ring-opening occurs, but benzene is formed by dehydrogenation. At high temperature (700 – 800 °C) cyclohexane decomposes to butadiene and other products. Aluminum chloride readily isomerizes cyclohexane to methylcyclopentane [7].

The most important commercial reaction of cyclohexane is its liquid-phase *oxidation* with air in the presence of soluble cobalt or boric acid catalysts to produce a mixture of cyclohexanol and cyclohexanone (KA oil) (→ Cyclohexanol

and Cyclohexanone, Chap. 3.2.). Cyclohexanol is oxidized to cyclohexanone, which is used to produce caprolactam, a monomer for nylon-6 production (→ Caprolactam, Chap. 4.; → 4. Fibers, Synthetic Organic). Alternatively, KA oil can be converted to adipic acid and hexamethylenediamine, the monomers for nylon-66 production (→ Adipic Acid; → Hexamethylenediamine) [8].

4. Production

Virtually all cyclohexane is produced commercially by hydrogenation of benzene (→ Benzene, Chap. 10.). A small amount is produced by superfractionation of the naphtha fraction from crude oil. Naturally occurring cyclohexane can be supplemented by fractionating methylcyclopentane from naphtha and isomerizing it to cyclohexane.

4.1. Hydrogenation of Benzene

Benzene can be hydrogenated catalytically to cyclohexane in either the liquid or the vapor phase in the presence of hydrogen. Several cyclohexane processes, which use nickel, platinum, or palladium as the *catalyst*, have been developed. Usually, the catalyst is supported, e.g., on alumina, but at least one commercial process utilizes Raney nickel.

Hydrogenation proceeds readily and is highly exothermic ($\Delta H_{500\,\mathrm{K}} = -216.37$ kJ/mol). From an equilibrium standpoint, the *reaction temperature* should not exceed 300 °C. Above this, the equilibrium begins to shift in favor of benzene so that high-purity cyclohexane cannot be produced. As a result of these thermodynamic considerations, temperature control of the reaction is critical to obtaining essentially complete conversion of benzene to cyclohexane.

Temperature control requires economic and efficient heat removal. This has been addressed in a number of ways by commercial processes. The earlier vapor-phase processes used multistage reactors with recycle of cyclohexane as a diluent to provide a heat sink, staged injection

of benzene feed between reactors, and interstage steam generators to absorb the exothermic heat of hydrogenation [9], [10]. In the 1970s processes have been developed that use only one reactor [11], [12] or a combination of a liquid- and a vapor-phase reactor [13]. The objectives of the later processes were to reduce capital cost and improve energy utilization. However, all of the commercial processes have comparably low capital cost and good energy efficiency.

A generalized flow scheme for a *vapor-phase process with multistage reactors* in series is shown in Figure 1. Benzene feed is divided and fed to each of the first two reactors. Recycled cyclohexane is introduced to the first reactor along with hydrogen. The recycled cyclohexane enables higher conversion in the reactors by absorbing part of the heat of hydrogenation. Steam generators between the reactors remove the heat of hydrogenation. The outlet temperature of the last reactor is controlled to achieve essentially 100 % conversion of benzene to cyclohexane. The effluent from the last reactor is cooled, and the vapor and liquid are separated. Part of the hydrogen-rich vapor is recycled to the first reactor, and the rest is purged to fuel gas or hydrogen recovery facilities. The liquid from the separator goes to a stabilizer where the overhead gas is sent to fuel gas; the remaining material is cyclohexane product, part of which is recycled to the first reactor.

A simplified flow scheme for a *process with liquid- and vapor-phase reactors* is provided in Figure 2. Benzene and hydrogen are fed to the liquid-phase reactor, which contains a slurry of finely divided Raney nickel. Temperature is maintained at 180 – 190 °C by pumping the slurry through a steam generator and by vaporization in the reactor. Roughly 95 % of the benzene is converted in this reactor. The vapor is fed to a fixed-bed reactor where the conversion of benzene is completed. The effluent from the

∗ To hydrogen recovery (optional).

Figure 2. Liquid- and vapor-phase reactor process
a) Liquid-phase reactor; b) Vapor-phase reactor; c) Separator drum; d) Compressor; e) Stabilizer
∗ To hydrogen recovery (optional).

fixed-bed reactor is processed as described previously for the vapor-phase process.

Benzene hydrogenation is done typically at 20 – 30 MPa. The maximum reactor temperature is limited to ca. 300 °C so that a typical specification of < 500 mg/kg benzene and < 200 mg/kg methylcyclopentane in the product can be achieved. This is necessary because of the thermodynamic equilibrium between cyclohexane – benzene and cyclohexane – methylcyclopentane. Actually, equilibrium strongly favors methylcyclopentane, but the isomerization reaction is slow enough with the catalysts employed to avoid a problem if the temperature is controlled.

The *hydrogen content* of the makeup hydrogen has no effect on product purity but it does determine the makeup, recycle, and purge gas rates. Streams with as low as 65 vol % hydrogen can be used.

Carbon monoxide and sulfur compounds are *catalyst deactivators.* Both can be present in the hydrogen from catalytic naphtha reformers or ethylene units, which are typical sources of makeup hydrogen. Therefore, the hydrogen-containing stream is usually passed

through a methanator to convert carbon monoxide to methane and water. Prior to methanation, hydrogen-containing gas can be scrubbed with caustic to remove sulfur compounds. Commercial benzene contains less than 1 mg/kg sulfur. In some cases, the recycle gas is also scrubbed with caustic to prevent buildup of hydrogen sulfide from the small amount of sulfur in the benzene. With properly treated hydrogen and specification benzene, a catalyst life in excess of three years can be achieved easily in fixed-bed reactors that use noble-metal catalysts supported on a base. The catalyst in the process that uses Raney nickel in suspension is reported to have a typical life of about six months before it must be replaced [14].

4.2. Separation from Naphtha

The cyclohexane content of the naphtha fraction of crude oil can vary from 0.5 to 5.0 vol %. However, *n*-hexane, isohexanes, methylcyclopentane, benzene, and dimethylpentanes have normal boiling points very close to cyclohexane; and the freezing points of cyclohexane and benzene are separated by $< 2\,°C$. Consequently, recovery of cyclohexane from naphtha by distillation or crystallization is difficult and uneconomic.

Cyclohexane can be separated from benzene by solvent extraction or extractive distillation, but no practical solvent system has been developed for separating cyclohexane from hexanes or methylcyclopentane. Trace quantities of benzene and *n*-hexane can be removed with zeolite X and zeolite A sieves, respectively. The difficulty of separating cyclohexane from naphtha is underscored by the fact that only one company, Phillips Petroleum, produces cyclohexane by distillation (ca. 10 % of U.S. capacity). This route is not used commercially elsewhere in the world.

4.3. Cost Considerations

The investment for a benzene hydrogenation unit that produces 100 000 t/a of cyclohexane was ca. $(5-7) \times 10^6$ \$ for a unit completed in 1985. This excludes investment for hydrogen recovery or manufacture and associated facilities, such as utility systems and tankage.

The net operating cost is low because of recovery of the heat of hydrogenation by steam generation and heat integration. The major costs are maintenance expenses, labor, capital recovery charges for the plant and working capital,benzene feedstock, and hydrogen (→ Hydrogen). The cost of hydrogen can vary widely and can affect cyclohexane manufacturing cost by as much as \$ 40 /t.

The selling price of cyclohexane is tied to the selling price of benzene. In the early 1980s, its price was ca. \$ 100 /t above the benzene price.

5. Quality Specifications and Tests

The typical purity specification for cyclohexane is 99.9 wt % min. Impurities are unconverted benzene, aliphatic hydrocarbons in the benzene feed to the hydrogenation unit, methylcyclopentane formed by isomerization of cyclohexane, and methylcyclohexane formed by hydrogenation of the small amount of toluene in benzene. Freezing point, relative density, and a distillation range of 1 °C, with 80.7 °C in the range, are generally specified. A sulfur level of less than 1 mg/kg as measured by ASTM method D-3120 is also specified. In addition, specifications of phenol, chloride, and basic nitrogen content exist, but they are of little importance because the levels of these in product cyclohexane are generally less than 0.1 mg/kg. Although these specifications, with the appropriate ASTM test method, are used in contractual agreements between cyclohexane producers and their customers, gas chromatography is generally employed for quality control in manufacturing because of its precision and reproducibility.

6. Uses, Economic Aspects

Over 98 % of the cyclohexane produced is used to make nylon intermediates: adipic acid, caprolactam, and hexamethylenediamine, with the first two consuming ca. 95 % of the cyclohexane used in nylon manufacture. Minor miscellaneous uses, such as solvents and polymer reaction diluents, consume the remainder of the cyclohexane produced.

Estimated worldwide production capacity and consumption of cyclohexane are given in Table 7. Consumption dropped significantly in

Table 7. Estimated production capacity and consumption of cyclohexane, in 10^3 t/a

Year	Capacity *				Consumption			
	United States	Western Europe	Japan	World	United States	Western Europe	Japan	World
1979					1000	750	510	3150
1980					785	600	500	2850
1981					720	650	480	2800
1982	1480	940	580	4250	470	600	430	2465
1983	1510	940	580	4280	665	725	460	2890
1984	1330	940	530	4050	860	710	480	3140
1995	1400	1100	740	5100				

* At end of year.

the early 1980s because of the generally depressed economy. The future growth in cyclohexane consumption is forecast to be 2 – 3 % /a. Its growth is limited because nylon is a mature product and other routes to nylon intermediates, which use butadiene, acrylonitrile, or phenol, have been developed. The utilization of cyclohexane recovered to slightly over 75 % of capacity in 1984 because consumption increased and several units were shut down.

7. Homologues

7.1. Cyclohexene

Cyclohexene can be used to synthesize many interesting products of potential commercial value. However, no viable process has been developed for producing it in large volume. The reason for this is the difficulty in hydrogenating benzene to cyclohexene because the ΔG° (298 K) for converting benzene to cyclohexene is -22.8 kJ/mol, which is considerably less than that for benzene to cyclohexane [ΔG° (298 K) = -97.9 kJ/mol]. Consequently, the hydrogenation reaction tends to go all the way to cyclohexane.

Despite the thermodynamic difficulty, considerable work on heterogeneous catalyst systems has been reported [15–18]. Ruthenium-based systems appear to be the best, but selectivities for cyclohexene are < 30 %; the rest of the product is cyclohexane.

7.2. Methylcyclohexane

The primary use of methylcyclohexane is as a component in the feed to catalytic naphtha reformers where it is readily dehydrogenated to toluene, a high-octane motor gasoline component. Some methylcyclohexane is used for solvent applications in which it is one component of a narrow boiling range fraction of naphtha. Like cyclohexane, it can be produced easily by hydrogenation of toluene, but no current market exists for large-scale quantities.

7.3. Methylcyclopentane

The primary use of methylcyclopentane, like methylcyclohexane, is as a component in the feed to catalytic naphtha reformers where it is isomerized to cyclohexane and, in turn, dehydrogenated to benzene. Methylcyclopentane is a minor component in some light aliphatic solvents, but it is not produced as a pure component in significant volume.

8. Toxicology and Occupational Health

Cyclohexane is mildly irritating to the skin. Both the TLV – TWA and MAK are 200 ppm, 700 mg/m^3; the TLV – STEL was listed in 1986 – 1987 as (375 ppm), (1300 mg/m^3), with a note of intention to delete this value [19], [20]. At levels above the TWA, cyclohexane can cause irritation of the eyes and mucous membranes. When high concentrations are inhaled, narcosis may occur. In contrast to benzene, little or no effect on the blood, even after long exposure, has been reported.

Methylcyclohexane is somewhat less narcotic than cyclohexane so a higher TLV – TWA of 400 ppm, 1600 mg/m^3 has been established; the MAK is 200 ppm, 810 mg/m^3; the TLV – STEL was (500 ppm), (2000 mg/m^3)

in 1986 – 1987, with the same notation as for cyclohexane. The toxic properties of cyclohexene (TLV – TWA and MAK of 300 ppm, 1015 mg/m^3) and methylcyclopentane (TLV and MAK have not been established) are thought to be similar to those of cyclohexane.

1. Introduction

Cyclohexanol [*108-93-0*], $C_6H_{11}OH$, M_r 100.16, is a colorless substance forming hygroscopic crystalline needles having a camphor-like odor. It is very soluble in alcohols, ketones, ethers, and alicyclic and aromatic hydrocarbons. In its pure state, it melts near room temperature, 25.15 °C. Cyclohexanone [*108-94-1*], $C_6H_{10}O$, M_r98.15, is a colorless to pale yellow liquid having an odor similar to that of acetone. It is also very soluble in most organic solvents.

Both cyclohexanol and cyclohexanone are produced on a large commercial scale. The vast majority of these compounds and their mixtures is consumed in the production of caprolactam and adipic acid, intermediates in the manufacture of nylon 6 and nylon 66 (→ Adipic Acid; → Caprolactam; → 4. Fibers, Synthetic Organic).

2. Physical and Chemical Properties

Physical Properties. The most important physical properties of cyclohexanol and cyclohexanone are shown in Table 1.

Chemical Properties. *Cyclohexanol* undergoes chemical reactions typical of secondary alcohols. It can esterify most organic acids or acyl halides, whereas halogen acids convert the alcohol to the corresponding cyclohexyl halide. Dehydration with sulfuric acid or vapor-phase treatment with alumina at 300 – 400 °C leads to cyclohexene. Mild oxidation or catalytic dehydrogenation gives cyclohexanone. Stronger oxidizing agents, such as nitric acid, give a good yield of adipic acid.

Cyclohexanone undergoes most of the reactions expected of aliphatic ketones. At room temperature, 0.02 % exists in the enol form [1]. Cyclohexanone reacts with bisulfite to give the addition product; it also reacts with hydrogen cyanide to give the cyanohydrin. It can be hydrogenated to cyclohexanol and under more vigorous conditions is further reduced to cyclohexane. Reactions with chlorine or bromine lead to substitution at either or both of the 2- and 6-positions. It readily undergoes base-catalyzed Aldol condensation with itself or with other aldehydes or ketones. The most important commercial reactions of cyclohexanone are with hydroxylamine to give cyclohexanone oxime (an intermediate on the way to caprolactam) and its oxidation with nitric acid to give adipic acid.

3. Production

Cyclohexanol and cyclohexanone were first produced on an industrial scale by the hydrogenation of phenol. This was followed in the 1940s by transition metal-catalyzed liquid-phase air oxidation of cyclohexane, which gave a mixture of cyclohexanol and cyclohexanone, the ratio of which could be partially controlled by the choice of metal catalyst. In the 1950s, Scientific Design developed a boric acid modified liquid-phase air oxidation of cyclohexane. This process, in which the intermediate cyclohexyl hydroperoxide was trapped as the peroxoborate ester, led to a higher yield and a higher ratio of cyclohexanol to cyclohexanone. Around 1990, Asahi commercialized the production of cyclohexanol from cyclohexene, an intermediate obtained from the partial hydrogenation of benzene.

Table 1. Physical properties of cyclohexanol and cyclohexanone

Property	Cyclo-hexanol	Cyclo-hexanone
mp, °C	25.15	−47
bp, °C	161.1	156.4
Vapor pressure, kPa	0.15 (20 °C) 0.48 (35 °C)	0.52 (20 °C)

With water: bp, °C	97.8	96.6
composition, water : compound	80 : 20	56 : 44
With phenol: bp, °C	183	
composition, phenol : compound	87 : 13	

Cyclohexanone can be prepared by dehydrogenation of cyclohexanol; the reverse reaction, hydrogenation of cyclohexanone to cyclohexanol, is also practical although not commercially practiced. Most large-scale cyclohexanol/cyclohexanone facilities employ some form of cyclohexane oxidation technology. The only remaining large phenol-based plants belong to DSM in Holland and Allied in the United States. Asahi has the only commercial cyclohexene-based plant, and there are reports of planned expansions at that facility in Japan as well as building a new plant in China.

3.1. Hydrogenation of Phenol

The product of phenol hydrogenation, i.e., cyclohexanol, cyclohexanone, or a mixture of the two, is determined by the metal catalyst. *Cyclohexanol* can be prepared in high yield by either vapor- or liquid-phase hydrogenation of phenol. Vapor-phase hydrogenation can be carried out by using a supported nickel catalyst or a nickel catalyst containing copper, cobalt, or manganese. The support is usually alumina or silicic acid. Yields as high as 98 % have been reported [2–5]. A flow diagram of the vapor-phase hydrogenation is shown in Figure 1.

Figure 1. Vapor-phase phenol hydrogenation process
a) Phenol evaporator; b) Hydrogenation reactor; c) Condenser; d) Low-boiler removal column; e) Cyclohexanol/cyclohexanone recovery column

Hydrogenation of phenol to *cyclohexanone* can be carried out in the vapor phase with a large variety of supported noble metal catalysts, including palladium, platinum, iridium, ruthenium, rubidium, and osmium. The hydrogenation is normally carried out at 140 – 170 °C and atmospheric pressure. Yields as high as 95 % at 100 % conversion can be obtained [6], [7].

Commercial liquid-phase hydrogenation of phenol under mild conditions with a palladium on carbon catalyst gives greater than 99 % yield of cyclohexanone at 90 % conversion [8]. By adjusting the operating conditions and changing to a Raney nickel catalyst, 99.9 % selectivity for cyclohexanol can be achieved [9]. Hydrogenation conditions can be adjusted to produce the mixture of cyclohexanol and cyclohexanone that is preferred by adipic acid producers.

3.2. Liquid-Phase Oxidation of Cyclohexane

The liquid-phase air oxidation of cyclohexane [*110-82-7*] to cyclohexanol and cyclohexanone was developed in the 1940s. The oxidation is usually carried out, either uncatalyzed or with a soluble cobalt catalyst, in a series of agitated reactors at 140 – 180 °C and at 0.8 – 2 MPa, although a single tower oxidizer can be used [10], [11]. The total residence time in the oxidizers is 15 – 60 min. Some of the initially formed cyclohexyl hydroperoxide [*766-07-4*](Eq. 1) is converted in the oxidizers to cyclohexanol, cyclohexanone, and byproducts (Eq. 2).

$$C_6H_{12} + O_2 \longrightarrow C_6H_{11}OOH \quad (1)$$

$$3\,C_6H_{11}OOH \longrightarrow 2\,C_6H_{11}OH + C_6H_{10}O + H_2O + O_2 + \text{byproducts} \quad (2)$$

The cyclohexanol to cyclohexanone ratio exiting the air oxidizers can be altered by the choice of catalyst used in the air oxidizer. The normal cobalt-catalyzed air oxidation and ″deperoxidation″ gives a cyclohexanol to cyclohexanone ratio of about 3.5. If chromium(III) is added to the air oxidizer, it appears to promote dehydration of cyclohexyl hydroperoxide to cyclohexanone and water, as opposed to the free-radical decomposition mechanism of cobalt, leading to a lower cyclohexanol to cyclohexanone ratio [12–14].

Because the intermediate cyclohexyl hydroperoxide and the products, cyclohexanol and cyclohexanone, are more readily oxidized than cyclohexane, the conversion of cyclohexane in the air oxidizers must be kept low (usually under 6 %) to maximize yield. Depending on the conversion, the total yield of alcohol, ketone, and hydroperoxide varies from 70 to 90 %. Byproducts of the oxidation include a wide range of mono- and dicarboxylic acids, esters, aldehydes, and other oxygenated materials.

To maximize overall yield of cyclohexane to the alcohol and ketone, most companies try to maintain a high percentage of the oxidized cyclohexane leaving the oxidizers as cyclohexyl hydroperoxide. To maximize the amount of cyclohexyl hydroperoxide leaving the air oxidizers, the oxidation can be carried out uncatalyzed or with a modified catalyst that minimizes hydroperoxide decomposition in the oxidizer [15–20]. This permits cyclohexyl hydroperoxide to be decomposed into cyclohexanol and/or cyclohexanone under milder conditions and in higher yields than if it had occurred in the air oxidizer.

For example, the air oxidation product may or may not be washed with water followed by conversion of cyclohexyl hydroperoxide to cyclohexanol and cyclohexanone with a homogeneous or heterogeneous metal catalyst [21–35]. Another method of decomposing the hydroperoxide is to contact it with an aqueous caustic phase containing a few parts per million of cobalt, which decomposes the hydroperoxide in high yield to the ketone and alcohol [36–41]. This caustic decomposition process can result in a lower alcohol to ketone ratio in the final product. A flow diagram of this caustic process is shown in Figure 2.

Table 2. Ratio of cyclohexanol to cyclohexanone produced from cyclohexyl hydroperoxide

Solution ∗ – Modification	Catalyst	Temperature, °C	Ratio ∗∗
A	none	155	0.8
A	Cr	155	0.4
A	Ni	155	1.4
A	V	155	1.4
A	Co	155	3.0
A	Mn	155	3.3
B	Co	160	2.5
A – hydrogenation of **1**	Pd	150	5 – 10
A – separate caustic aqueous phase	Co	120	0.2

∗ A = cyclohexyl hydroperoxide (**1**) in cyclohexane; B = **1** in air oxidizer tails.
∗∗ Cyclohexanol : cyclohexanone.

Several patents report that cyclohexyl hydroperoxide in the oxidizer effluent can be hydrogenated in high yield to cyclohexanol [42–47].

Figure 2. Cyclohexane oxidation/caustic decomposition process
a) Air oxidizers; b) Water wash decanter; c) Decantation; d) Caustic decomposition reactor; e) Caustic decantating; f) Cyclohexane recovery column; g) Cyclohexanol/cyclohexanone recovery column

Table 2 shows the cyclohexanol to cyclohexanone ratio that can be obtained by using a range of conditions and a variety of hydroperoxide decomposition methods.

3.3. Boric Acid Modified Oxidation of Cyclohexane

In the 1950s, Scientific Design (now Halcon International) developed a process in which anhydrous metaboric acid [*13460-50-9*]was added as a slurry to the first of several staged air oxidation vessels (see Figure 3) [48], [49]. The cyclohexyl hydroperoxide formed is trapped as the cyclohexyl perborate ester (Eq. 3). The perborate ester then reacts with additional cyclohexane in the air oxidizer to yield the borate ester and additional cyclohexanol (Eq. 4). This borate ester is relatively stable in the air oxidizer and is protected from over oxidation to ring-opened products. The ester is subsequently hydrolyzed to cyclohexanol and boric acid [*10043-35-3*](Eq. 5). The boric acid is dehydrated to metaboric acid and is recycled to the air oxidizer (Eq. 6).

$$18\,C_6H_{12} + 9\,O_2 + 2\,H_3B_3O_6 \longrightarrow 6\,B(OOC_6H_{11})_3 + 12\,H_2O \quad (3)$$

$$B(OOC_6H_{11})_3 + 3\,C_6H_{12} \longrightarrow B(OC_6H_{11})_3 + 3\,C_6H_{11}OH \quad (4)$$

$$B(OC_6H_{11})_3 + 3\,H_2O \longrightarrow 3\,C_6H_{11}OH + H_3BO_3 \quad (5)$$

$$3\,H_3BO_3 \longrightarrow H_3B_3O_6 + 3\,H_2O \quad (6)$$

The chemistry of this process is very similar to the metal-catalyzed oxidation except that the cyclohexyl rings are protected from further attack. Compared to other commercial processes, the boric acid process is characterized not only by a higher investment and a higher operating cost (to recover and recycle the boric acid), but also by a higher yield of cyclohexanol and cyclohexanone (up to 88 %) and an alcohol to ketone ratio as high as 10 : 1. The technology was further developed by Institut Français du Pétrole [50], [51]. The Halcon process has been licensed to several companies around the world. The major producers using this technology today are Solutia, DuPont (UK), Bayer, and Mitsubishi. The original plant at Rhône-Poulenc, based on this technology, was now shut down.

3.4. Production and Hydration of Cyclohexene

In 1972 the first patent covering the selective hydrogenation of benzene [*71-43-2*] to cyclohexene [*110-83-8*] appeared [52]. Shortly thereafter, two patents described the hydration of cyclohexene to cyclohexanol by using various catalysts [53], [54]. Since then, a large number of patents have appeared worldwide. In 1990, Asahi commercialized this process with a 100 t/a

Figure 3. Boric acid modified oxidation of cyclohexane

Figure 4. Partial hydrogenation of benzene to cyclohexene, followed by hydration to cyclohexanol
a) Benzene purification; b) Partial hydrogenation; c) Separation of unconverted benzene from cyclohexene and cyclohexane; d) Separation of cyclohexene from cyclohexane; e) Separation of cyclohexene from extractive solvent; f) Hydration of cyclohexene; g) Recycle of unconverted cyclohexene; h) Purification of cyclohexanol

plant in Japan. The process involves three primary steps: the selective hydrogenation of benzene; the separation of the cyclohexene from the unconverted benzene and the over-hydrogenation product cyclohexane; and the hydration of the cyclohexene (Fig. 4).

The hydrogenation is carried out with a specially prepared heterogeneous nickel catalyst. The reaction is run to about 50 % conversion, at which point the product consists of about 35 % cyclohexene, 15 % cyclohexane, and 50 % unconverted benzene. The selectivity is very sensitive to impurities such as sulfur and iron. For this reason the benzene must be specially purified and the hydrogenation vessel lined with an inert material [55–58].

The mixture of cyclohexane, cyclohexene, and benzene can not be distilled but must go through two successive extractive distillations. The best solvent to use in these distillations has been the subject of numerous patents [59–62]. The recovered cyclohexane could be converted back to benzene, but is probably sold to other caprolactam and adipic acid manufacturers.

The hydration of cyclohexene is also performed with a heterogeneous catalyst in a slurry

reactor. The extent of hydration is limited by the equilibrium constant, which would restrict conversion to about 14 %. The use of several additives to increase the conversion of cyclohexene to cyclohexanol has also been patented [63–68].

The yield of this process from benzene to cyclohexanol is extremely high, probably greater than 95 %. Although byproducts are not a concern, the investment is significantly higher than that of a conventional cyclohexane oxidation plant. The fact that the product is cyclohexanol, not cyclohexanone, could make it unattractive as the basis for a caprolactam plant.

3.5. Dehydrogenation of Cyclohexanol

Cyclohexanol can be dehydrogenated to cyclohexanone (the desired starting material for caprolactam manufacture) without catalyst by passing the vapors through a tube furnace at 400 – 450 °C. The vapors are cooled, the hydrogen separated, and the cyclohexanone, which contains cyclohexene and water, is purified in a distillation column. The purity of the resulting cyclohexanone is 98 – 99 % [69–72].

The catalytic dehydrogenation, which is generally practiced, can be carried out under milder conditions and in better yield over a variety of catalysts, including chromium oxide – copper [73], copper chromate [74], nickel [75], [76], zinc sulfide, and zinc – iron catalyst [77–79], cobalt carbonate [80], and other metals [81].

4. Plant Safety

The major industrial hazard associated with producing cyclohexanol and cyclohexanone is oxidation of cyclohexane at elevated temperature and pressure. Inside the air oxidation unit, the vapor is usually too rich in fuel (cyclohexane) to be explosive. However, in the air inlet piping, an explosive mixture can result if hot cyclohexane backs up into this system. Some of the solids formed in the oxidation, usually called ″coffee grounds,″ can be pyrophoric. At least one incident occurred in which the air sparger, entering the oxidizer, was observed to be ″glowing red,″ indicating a fire inside the sparger. An incident of a fire inside an oxidizer at the sparger nozzles has been reported by ICI.

A sudden release of the hot cyclohexane to the atmosphere, (e.g., from the rupture of a process line or a break in the air oxidation vessel itself) results in an extremely hazardous situation. An incident of this type occurred at a Monsanto plant at Pensacola, Florida in 1971. Fortunately, the resulting vapor cloud was dispersed by the prevailing winds before it could ignite.

In 1974, a much more serious incident occurred at a Nipro plant in Flixborough, England. A section of 50-cm pipe connecting two air oxidation vessels ruptured, resulting in the release of a large cloud of cyclohexane vapor. About 30 s after the break occurred, the vapor cloud ignited, and the resulting explosion destroyed the plant. A total of 28 lives were lost.

5. Quality Specifications and Chemical Analysis

High-grade commercial cyclohexanol, usually obtained from hydrogenation of phenol, has the following specifications:

mp	19 – 23 °C
bp	159 – 162 °C
Water content	0.1 %
Phenol content	0.0001 %

The best analytical method for cyclohexanol is gas chromatography with Carbowax 20M on Chromosorb. Common impurities, such as cyclohexane, cyclohexanone, phenol, pentanol, and benzene, do not interfere. Cyclohexanol can be characterized as the 4-nitrobenzoyl derivative, *mp* 52 °C. It can be determined colorimetrically by using a solution of 4-hydroxybenzaldehyde in sulfuric acid [82]. The preferred acylating agent for microscale quantities is acetic anhydride [83].

Commercial cyclohexanone is available in several grades. A typical material is colorless to pale yellow, contains 98 – 99 % cyclohexanone and 0.2 % water, and has a boiling range of 151 – 157 °C.

Cyclohexanone, like cyclohexanol, is best analyzed by using a Carbowax 20M on Chromosorb gas chromatography column. Cyclohexanone can be characterized as the oxime (*mp* 90.5 °C), the semicarbazone (*mp* 167 °C), or the nitrophenylhydrazone (*mp* 146 °C). It can be

quantitatively determined by reaction with hydroxylamine hydrochloride, followed by basic titration of the hydrogen chloride that is liberated [84], [85].

6. Storage and Transportation

Cyclohexanol and cyclohexanone are not corrosive to iron or steel and can be stored or transported in drums, tank trucks, or tank cars. An inert gas (nitrogen) blanket is not required. The U.S. DOT classifies both cyclohexanol and cyclohexanone, or mixtures thereof, as hazardous flammable liquids. For transportation, they must be labeled flammable and marked Hazard Level III [86]

7. Uses and Trade Names

Cyclohexanol has numerous industrial applications, the major two being as an intermediate in the production of adipic acid (for use in nylon 66) and cyclohexanone, which is then converted to caprolactam (the monomer for nylon 6). The U.S. market for refined cyclohexanol, other than as a nylon intermediate was 10×10^3 t in 1992 [87]. The major uses are:

1) As a solvent for lacquers, varnishes, oils, alkyd resins, gums, shellacs, ethyl cellulose, acid dyes, and natural resins
2) In the preparation of esters for plasticizers, e.g., dicyclohexyl phthalate
3) In the laundry industry and in soaps and synthetic detergents as a homogenizer and stabilizer
4) In paint and varnish removers
5) In the insecticide, fragrance, polish, and rubber cement industries

Trade names: Cyclohexyl Alcohol, Hexahydrophenol, Hydrophenol, Hexalin, and A.

Cyclohexanone. Over 97 % of all cyclohexanone produced is oxidized to adipic acid or converted to cyclohexanone oxime, which is then rearranged with sulfuric acid to caprolactam. Other uses for cyclohexanone include thinner or solvent for synthetic resins, polymers, and lacquers. It is also used as a starting material in the synthesis of many insecticides, herbicides, and pharmaceuticals, as well as being a good solvent for many insecticides.

Trade names: Hexanon, Hydrol-O, Sextone, Pimelic Ketone, Ketohexamethylene, and K.

8. Derivatives

8.1. Esters of Cyclohexanol

Numerous esters of cyclohexanol are of commercial significance, the more important being dicyclohexyl phthalate, dicyclohexyl adipate, and cyclohexyl acrylate.

Dicyclohexyl phthalate [*84-61-7*], $C_{20}H_{26}O_4$, M_r 330.45, *mp* 65 °C, *bp* 218 °C (0.6 kPa), d^{20} 1.148. This diester is normally prepared from the reaction of phthalic anhydride with cyclohexanol in an inert solvent like toluene at ca. 130 °C.

Dicyclohexyl phthalate is used as a plasticizer to modify the properties of synthetic resins, in alkyd resins and cellulose nitrate to increase their stability to light and weathering, and to improve the chemical and physical properties of plastics by preventing creep. It is very stable to heat and light and imparts a glossy finish to extruded materials. It is also used in paper finishes and makes printers ink water-resistant.

Dicyclohexyl adipate [*849-99-0*], $C_{18}H_{30}O_4$, M_r 294.50, *mp* 35.5 °C, *bp* 324 °C, d^{20} 1.037, n^{20} 1.4720.

This diester can be prepared by esterification of adipic acid, transesterification of dimethyl adipate, or direct reaction of adipic acid with cyclohexene [65]. It is used as a plasticizer in vinyl copolymers, polystyrene, and paints. A patent indicates that it can be oxidized in high yield to adipic acid [88].

8.2. Cyclohexanone Oxime

Cyclohexanone oxime [*100-64-1*], $C_6H_{10}NOH$, M_r 113.16 , *mp* 90.5 °C, *bp* 204 °C, sublimes at room temperature (0.6 kPa); it is a white crystalline solid that can be crystallized as prisms from hydrocarbon solvents. This compound is

the most important commercial derivative of cyclohexanone. It can be prepared by warming cyclohexanone with an aqueous mixture of hydroxylamine hydrochloride and sodium bicarbonate. The oxime undergoes a Beckmann rearrangement in the presence of sulfuric acid to give caprolactam.

Large commercial quantities of cyclohexanone oxime are used in the preparation of caprolactam, the intermediate for the preparation of nylon 6. The cyclohexanone oxime can also be reduced to a mixture of cyclohexylamine and dicyclohexylamine or it can hydrolyzed to cyclohexanone.

8.3. Methylcyclohexanols and Methylcyclohexanones

Methylcyclohexanol, $CH_3C_6H_{10}OH$, M_r 114.19, is usually available as a mixture of the cis and trans isomers of 2-, 3-, and 4-methylcyclohexanol. These derivatives are prepared by hydrogenation of individual or mixed cresols. Table 3 gives the physical properties of the individual isomers and of a commercial mixture.

The commercial mixture is a colorless liquid and is used as a solvent for resins, oils, and waxes, as a blending agent in soaps, and as an antioxidant in lubricants [89], [90].

Methylcyclohexanone is normally sold as a mixture of three isomers (2-, 3-, and 4-methylcyclohexanone). The individual isomers can be isolated; their physical properties, along with those of a commercial mixture, are listed in Table 3.

Methylcyclohexanones can be prepared by mild oxidation of the corresponding alcohols or by direct hydrogenation of cresol in a process similar to the hydrogenation of phenol to cyclohexanone.

The technical-grade commercial mixture contains all three isomers. At 20 °C its solubility in water is 1.5 %, and 3 % water is soluble in the methylcyclohexanones. Methylcyclohexanones are used as solvents in the dye and resin industries.

8.4. Trimethylcyclohexanols and Trimethylcyclohexanones

3,3,5-Trimethylcyclohexanol (**2**), $C_6H_{18}O$, M_r 142.23, is a colorless, crystalline material, which is commercially produced as a mixture of the *cis* and *trans* isomers. The individual isomers can be separated by careful distillation or crystallization.

The physical properties of the two isomers are: *cis* isomer [*933-48-2*], *mp* 37.3 °C, n^{60} 1.4390, d^{60}0.860, vapor pressure 1.3 kPa (at 86 °C), flash point 88 °C, solubility in water 0.19 % (at 60 °C), water solubility in alcohol 4.0 % (at 60 °C); *trans* isomer [*767-54-4*], *mp* 57.3 °C, n^{60} 1.4390, d^{60}0.862, vapor pressure 1.3 kPa (at 76 °C), flash point 76 °C, solubility in water 0.17 % (at 60 °C), water solubility in alcohol 2.6 % (at 60 °C).

Trimethylcyclohexanol (**2**) is miscible in all proportions with most organic solvents. It is a cyclic alcohol with similar properties to cyclohexanol. Oxidation of trimethylcyclohexanol with nitric acid gives a mixture of 2,2,4-trimethyladipic acid and 2,4,4-trimethyladipic acid. Trimethylcyclohexanol is prepared by hydrogenating 3,5,5-trimethyl-2-cyclohexen-1-one [*78-59-1*] (**1**), isophorone (a condensation-product of acetone).

The best catalyst for the hydrogenation is nickel or a mixture of nickel and copper on either silica gel or alumina. The hydrogenation is carried out in high yield at 120 – 200 °C and 1 – 2 MPa. The byproducts of the reaction are small amounts of

Table 3. Physical properties of methylcyclohexanols and methylcyclohexanones

Isomer	CAS registry number	*mp*, °C	*bp*, °C	d^{20}	*n*	Flash point, °C

Commercial mixture	[*1331-22-2*]		165 – 171	0.918 – 0.925		

trimethylcyclohexanone, trimethylcyclohexane, and trimethylcyclohexene.

The most important use for the alcohol is as a feedstock for trimethyladipic acid [93–97]. This mixture of 2,2,4-trimethyladipic acid [*3586-39-8*]and 2,4,4-trimethyladipic acid [*3937-59-5*], is used in the manufacture of plasticizers and lubricants, and can be converted to dinitriles, diamines, or glycols. Other uses for trimethylcyclohexanol are as replacement for cyclohexanol in polishes and waxes. Because of its lower vapor pressure and unique structure, trimethylcyclohexanol is better than cyclohexanol in varnishes and shellacs.

The trimethylcyclohexanol that is sold commercially is a mixture of the cis and trans isomers. Analysis of a typical commercial product indicates 98 % trimethylcyclohexanols, 1 % trimethylcyclohexanone, 0.4 % trimethylcyclohexane, 0.3 % trimethylcyclohexene, 0.1 % isophorone, and 0.2 % water.

Trimethylcyclohexanol can be stored and transported in iron or steel drums, containers, tank cars, or tank trucks. It is stable indefinitely and does not need to be blanketed with an inert gas.

3,3,5-Trimethylcyclohexanone (**3**) [*873-94-9*], $C_6H_{16}O$, M_r 140.24, is a colorless liquid having properties similar to those of cyclohexanone. It has the following physical properties: *mp* −10 °C, *bp* 188.8 °C, d^{20} 0.888, n^{20} 1.4455, flash point 72 °C, solubility (at 20 °C) of ketone in water 0.3 %, water in ketone 1.4 %. It is miscible in all proportions with most organic solvents.

Trimethylcyclohexanone (**3**) is also prepared by hydrogenating trimethylcyclohexenone (**2**). However, the olefin hydrogenation can be carried out without hydrogenating the ketone by using a palladium-supported catalyst at 110 – 170 °C and 0.2 – 6 MPa [98]. The combination of catalyst, reaction conditions, and amount of hydrogen determines whether the ketone or alcohol is produced.

Trimethylcyclohexanone is a good solvent for low molecular mass poly(vinyl chloride)-type alkyd resins and for nitrocellulose. It can be used in place of methylcyclohexanone, where its higher boiling point results in superior performance in some applications.

9. Economic Aspects

The quoted price for technical-grade cyclohexanol in February 1999 was $ 1.83/kg [99] as compared to $ 1.32/kg in 1986 [100]. U.S. sales of cyclohexanol in 1992 were about 10×10^3 t [87], up from 4.3×10^3 t in 1971 [101]. The remaining Western world sales were believed to be about half of the U.S. sales.

In 1992, U.S. non-adipic acid, non-caprolactam sales of cyclohexanone were about 20×10^3 t, up from 15×10^3 t in 1970 [101]. The early 1999 cost of technical-grade cyclohexanone was $ 1.61/kg [99], whereas the quote

for the same material in November 1986 was $ 1.25/kg [100].

This sales volume for either chemical does not represent capacity, as the vast majority of both are consumed within the manufacturing companies to make adipic acid or caprolactam. In 1992, the worldwide capacity for cyclohexanol-cyclohexanone manufacture was about 3.2×10^6t. Of that total, about 58 % was used for caprolactam manufacture, 40 % for adipic acid manufacture, and the remainder was sold for other uses.

10. Toxicology and Occupational Health

Cyclohexanol and cyclohexanone are moderately toxic [102], but have no apparent carcinogenicity. For cyclohexanol the OSHA TLV for exposure to vapor for 8 h is 50 ppm [103]. The ACGIH has established TLV-TWA values for exposure to cyclohexanol vapor of 50 ppm, 200 mg/m^3 [104]. The TLV-TWA for cyclohexanone is 25 ppm, 100 mg/m^3. The MAKs for both compounds are 50 ppm, 200 mg/m^3.

Excessive exposure to vapor of either chemical results in irritation to the eyes, nose, and throat. Exposure of animals to a high concentration of cyclohexanol vapor resulted in irritation, lacrimation, salivation, lethargy, incoordination, narcosis, mild convulsions, and, in some cases, death. Degenerative changes were noted in the brain, kidney, and liver of rabbits exposed repeatedly to high vapor concentrations of cyclohexanol [102].

Exposure of animals to high concentrations of cyclohexanone vapor also resulted in irritation, lacrimation, and salivation. Decreased heart rate and depression of the CNS were also noted [105]. Degenerative changes were noted in the kidney and liver of monkeys and rabbits exposed repeatedly to high vapor concentrations of cyclohexanone.

For single dosages of cyclohexanol, the oral LD_{50} for rats is 2.06 g/kg [106] and the minimum lethal dose for rabbits is 2.4 g/kg [92]. With cyclohexanone, the oral LD_{50} for rats is 1.62 g/kg [107] and the minimum lethal dose for rabbits is 1.6 – 1.9 g/kg [92].

Cyclohexanol and cyclohexanone are moderately irritating to the eye and can cause corneal injury [107], [108]. Cyclohexanol can be absorbed through the skin in toxic amounts, and extensive exposure can cause tremors, narcosis, hypothermia, and death [92]. Cyclohexanone is only moderately irritating to the skin. Defatting and dermatitis of the skin occurred when animals were exposed for long periods of time [109].

Derivatives. Commercial *methylcyclohexanol* is low in toxicity, and the ACGIH has set TLVs of 75 ppm, 350 mg/m^3 (STEL) and 50 ppm, 235 mg/m^3 (8-h TWA). The MAK value is the same as the TLV/TWA value [91]. Excessive exposure causes headaches and eye and nose irritation.

Methylcyclohexanones are moderately toxic to laboratory animals and cause eye, nose, and throat irritation; they have produced corneal damage to the eyes of rabbits. The single-dose oral LD_{50} for rats is ca. 2 g/kg [92]. 2-Methylcyclohexanone may be absorbed through the skin. Its TLV/TWA and MAK are 50 ppm, 230 mg/m^3; the TLV/STEL is 75 ppm, 345 mg/m$^{3\cdot}$.

Trimethylcyclohexanol has the same toxicological properties as methylcyclohexanol, but because of its lower vapor pressure, it presents fewer hazards. Neither TLV nor MAK values have been adopted.

The toxicity of *trimethylcyclohexanone* is similar to that of methylcyclohexanone, but its lower vapor pressure makes it less dangerous to handle.

1. Cyclopentadiene and Dicyclopentadiene

The physical and chemical properties of cyclopentadiene and dicyclopentadiene have been reviewed elsewhere [1, pp. 417 – 429.], [2], [3], [4], [5].

1.1. Physical Properties

Cyclopentadiene [*542-92-7*], C_5H_6, M_r 66.10, is a colorless liquid having a sweet terpenic odor. It is also known as pentole and pyropentylene. It is soluble in most organic solvents, including ethanol, diethyl ether, acetone, petroleum ether, benzene, and toluene, but is relatively insoluble in water.

The boiling points and compositions of three hydrocarbon azeotropes with cyclopentadiene are listed below:

Second component	*bp* (0.1 MPa), °C	Cyclopentadiene, mole fraction
n-Pentane	35.3	0.31
2-Methyl-2-butene	38.0	0.37
cis-2-Pentene	36.9	0.03

Dicyclopentadiene [*77-73-6*], $C_{10}H_{12}$, M_r 132.20, colorless crystals, has a camphoraceous odor and is soluble in ethanol, diethyl ether, and acetic acid.

Table 1. Physical properties of cyclopentadiene and dicyclopentadiene

Physical property	Cyclopentadiene	Dicyclopentadiene

Additional properties are available [4–6]. The IR [7], ^{1}H NMR [8], and mass spectra [9] of cyclopentadiene and the ^{1}H NMR spectrum [10] of dicyclopentadiene have been reported.

1.2. Chemical Properties

Cyclopentadiene (**1**) is an extremely reactive compound. Neat, it can only be preserved at − 80 °C or below, and then only for a limited amount of time. At or above room temperature, it dimerizes spontaneously to give dicyclopentadiene (**2**).

1 **2**

The dimerization rate r_D is a function of temperature [1, p. 423]:

T, °C	−20	0	10	15	20	25	30	40
r_D, mol %/h	0.05	0.5	1	1.5	2.5	3.5	6	15

Above 160 °C, dicyclopentadiene dissociates into cyclopentadiene again. Therefore, cyclopentadiene is stored and handled as its stable dimer. The dimerization of cyclopentadiene is exothermic and may get out of control, leading to polymerization and even coking in sealed vessels that lack effective heat removal.

Reactions of cyclopentadiene with aggressive reagents, such as concentrated sulfuric acid, fuming nitric acid, or ozone, can lead to decomposition or even explosion, depending on the conditions, particularly the reagent/substrate ratio. If proper care is taken, however, selective reaction can be achieved with most reagents. Major reaction types are cycloadditions and additions to the double bonds, oligo- and polymerizations, substitutions at the reactive methylene group, and oxidations.

A variety of *cycloaddition reactions* have been realized (Fig. 1). The formation of **3** [11] and **4** [12] are examples of [2 + 2] and [2 + 3] cycloadditions, respectively. By far the most important and most versatile types are catalytic and noncatalytic [4 + 2] cycloadditions, the Diels – Alder reactions. They afford the ring systems **5**, **6**, **7**, **8**, and **9** by reaction of cyclopentadiene with monoolefins, olefinic esters [13], acetylenes [14], [15], conjugated diolefins [16], [17], [18], cumulated diolefins [19], aldehydes [20], and activated ketones [21]. The cycloaddition of glyoxylic acid with cyclopentadiene in aqueous solution leads to α-hydroxy-γ-lactones after rearrangement of the Diels – Alder adduct [22]. Diels – Alder reactions with monoolefins and acetylenes are particularly facile with substrates bearing one (R^1) or two (R^1 and R^2) electron-withdrawing groups, such as carbonyl-, cyano-, or halomethane moieties. With chiral boron catalysts, highly effective enantioselective Diels – Alder reactions of cyclopentadiene with acetylenic aldehydes can be carried out to give products of type **6** [23]. Using chiral monoalcohols such as isosorbide as starting materials to provide acrylate derivatives for Diels – Alder reactions with cyclopentadiene provides exclusively endo adducts with high diastereoselectivity [24]. Diels – Alder additions of cyclopentadiene with cyclic substrates afford tricyclic ring systems that exhibit predominantly endo geometry, as in the case of dicyclopentadiene (**12**) and the Diels – Alder adduct **13** of cyclopentadiene with maleic anhydride.

12

13

Compounds **10** [25] and **11** [26] are examples of [4 + 3] and [4 + 4] cycloaddition products of cyclopentadiene, respectively.

Addition reactions have been realized with a variety of reagents. Examples are the selective hydrogenation to give cyclopentene, hydrohalogenations to give 3-halocyclopentenes, catalyzed hydrocyanation to give cyanocyclopentene and dicyanocyclopentane [27], and halogenations to give 3,5-dihalocyclopentenes and 1,2,3,4-tetrahalocyclopentanes. Tetrachlorocyclopentane can be readily converted into hexachlorocyclopentadiene: catalytic chlorination of the tetrachlorocyclopentane gives octachlorocyclopentane, which is dehydrochlorinated.

Oligo- and polymerizations can be carried out thermally or catalytically. Thermal reactions have been reported to occur by a series of consecutive cycloadditions of cyclopentadiene with Diels – Alder adducts like **14** to give products of structure **15** [28], [29]. A special case is the thermally induced homopolymerization of cyclopentadiene via dicyclopentadiene (**12**) to give crystalline oligomers or amorphous polymers, depending on the reaction temperature and time. Polymerization of cyclopentadiene with cationic catalysts gives cross-linked elastomeric materials [30]; with Ziegler-type catalysts, these polymerizations give elastomers. In addition, numerous copolymers of cyclopentadiene, e.g., with aromatics and/or olefins, drying oils, and indene – coumarone resins, have been reported.

14 **15**

Substitution reactions at the reactive methylene group occur predominantly by initial deprotonation, giving the resonance-stabilized cyclopentadienyl anion, which exhibits quasiaromatic character. Products derived from it are organometallics, such as alkali-metal and Grignard compounds and especially transition-metal complexes. A variety of the latter have been synthesized following the discovery of ferrocene. Other notable substitution reactions at the methylene group are mono- and dialkylations with alkyl halides, base-catalyzed carboxylation with carbon dioxide, and base-catalyzed condensations with aldehydes and ketones to give fulvenes. The last has been used to prepare a wide variety of fulvenes by starting from acyclic, carbocyclic, and heterocyclic [31] carbonyl compounds in efficient, high-yield syntheses [32].

Oxidation reactions with molecular oxygen occur spontaneously and provide intractable peroxidic materials. Controlled photochemical oxidation with oxygen gives the cyclic peroxide **16** [33], which can be converted into **17**, **18**, or **19** by reduction. Reaction with oxygen in the gas phase catalyzed heterogeneously by various mixed metal oxides has been reported to produce maleic anhydride [34], [35] and in one case a mixture of maleic and phthalic anhydride [36]. Heterogeneously catalyzed ammoxidation of cyclopentadiene affords pyridine [37].

18

19

1.3. Production

Cyclopentadiene is available from coal tar as dicyclopentadiene in quantities of ca. 10 – 20 g per ton of coal and can be readily isolated [38]. Considerably larger quantities are available from steam cracking operations, e.g., of naphtha, which affords ca. 14 kg of dicyclopentadiene per ton of feed material [38–40]. In this case, the C_5 fraction of pyrolysis gasoline contains

Figure 1. Cycloaddition reactions of cyclopentadiene

ca. 25 wt % cyclopentadiene with approximately equal proportions of isoprene and of *n*-pentane, along with other C_5 hydrocarbons.

From the C_5 fraction, cyclopentadiene can be isolated by the sequence of steps shown in Fig. 2.

In the first step, cyclopentadiene is dimerized to give dicyclopentadiene by heat soaking the entire C_5 fraction, either at normal pressure and 30 – 100 °C over 5 – 24 h or at elevated pressure and 140 – 150 °C [38], [41]. In the second step, the remaining components of the original C_5 fraction, which have boiling points of 28 – 50 °C, are distilled overhead, and crude dicyclopentadiene (*bp* 172.8 °C) is obtained in 85 – 90 % purity [38] at the bottom of the column. In the third step, the crude dicyclopentadiene is monomerized, either in the liquid phase at 170 – 200 °C [39] or in the gas phase at 300 – 400 °C in the presence of diluents such as steam, hydrogen, nitrogen, or methane [1, p. 424], to give cyclopentadiene in ca. 95 % purity [38].

Figure 2. Block diagram for the separation of cyclopentadiene from a C_5 fraction

Cyclopentadiene can be further purified by sequential dimerizations under carefully controlled slow heat soaking [38] and subsequent monomerizations. This procedure largely avoids the codimerization of cyclopentadiene with residual unsaturated C_5 impurities, allowing the latter to be removed from dicyclopentadiene by stripping.

Alternative modes of formation of cyclopentadiene are heterogeneously catalyzed monomerizations of dicyclopentadiene [42], [43]; catalyzed dehydrocyclization of piperylene [44], [45]; catalyzed dehydrogenations of cyclopentene [46], [47] and cyclopentane [48]; catalyzed hydrodenitrification of pyridine, quinoline [49], and other aromatic amines [50]; the pyrolysis of phenol [51], [52]; and the pyrolysis of plastics and rubbers [53]. Another possibility for the isolation of cyclopentadiene from the C_5 fraction of pyrolysis gasoline is the selective formation of a Diels – Alder adduct by introducing the C_5 fraction into aqueous maleic acid. The pure Diels – Alder adduct precipitates, whereas the remaining dienes of the C_5 fraction do not react [54–56].

1.4. Uses

Cyclopentadiene is the single major precursor for the production of cyclopentene by selective hydrogenation. It is used as a prepolymer to modify the properties of Ziegler – Natta catalysts [57]. Ethylidenenorbornene (**8**; R = CH_3), which can be produced by Diels – Alder addition of cyclopentadiene with 1,2-butadiene or with 1,3-butadiene followed by isomerization of the ensuing adduct **7**, serves as a termonomer in the production of ethylene – propylene terpolymer elastomers. Polymerization of **8** occurs through the more reactive endocyclic double bond, whereas the exocyclic double bond imparts the active site for vulcanization. The facile reversibility of the Diels – Alder reaction has been used for the transient protection of α, β-unsaturated carbonyl compounds from polymerization while the compounds were chemically modified at or near the carbonyl functions [58]. By this method, isoprenic alcohols such as linalool and nerolidol have been synthesized in high yields starting from methyl vinyl ketone [59]. Substituted pentacycles such as **21**, which are readily obtained from Diels – Alder adducts **20** of cyclopentadiene with substituted paraquinones, have been shown to undergo facile acid-catalyzed ring opening to the tricyclic system **22**, which in turn is completely reconverted to **21** in the presence of light. Thus, the system bears prospects for light – energy conversion by storing energy in the strained pentacyclic system **21** [60]. Diels – Alder adducts of fulvenes with activated olefins have been converted into bicyclic ketones such as **23**, which are useful in perfume formulations. Complexes of the cyclopentadienyl anion with transition metals (metallocenes) such Ti, Zr, and Hf act as polymerization catalysts [61]. Several complexes with Ti, V, Nb, or Mo as central atom [62] and the Diels – Alder adducts of cyclopentadiene with anthraquinone derivatives [63] show cancerostatic activity.

20

21 **22**

23

Homopolymers of cyclopentadiene have been reported to be useful as modifiers for high molecular mass polymers as base materials for coatings, adhesives, paper-sizing agents, and printing inks. The Diels – Alder adduct **13** of cyclopentadiene and maleic anhydride is useful for the production of modified polyester resins [38].

Hexachlorocyclopentadiene, which was a substantial commercial product derived from cyclopentadiene, has decreased in importance considerably. Major products derived from it were the chlorinated pesticides aldrin, dieldrin, chlordane, and heptachlor, but their application has been drastically restricted due to their toxicity. Hexachlorocyclopentadiene has also been used for the preparation of flame- and fire-retardant chemicals. In particular, the Diels – Alder adduct with maleic anhydride has been used as a comonomer in the synthesis of fire-resistant polyesters. Other cyclopentadiene-containing resins are used, e.g., as serum and plasma separating layers for blood-testing containers [64] and for the production of synthetic lubricants [65].

Dicyclopentadiene has attracted attention as a building block for the production of modified hydrocarbon resins, which show increased reactivity in copolymerizations with drying oils and produce paint resins with improved drying rate, gloss, and hardness. Modifications of unsaturated polyester resins with dicyclopentadiene have also been reported [38]. Hydrogenation of dicyclopentadiene and subsequent acid-catalyzed isomerization of the ensuing saturated product **24** has opened a facile synthetic route to adamantane **25**.

24 **25**

2. Cyclopentene

The physical and chemical properties of cyclopentene have been reviewed elsewhere [66, pp. 593 – 605], [3].

2.1. Physical Properties

Cyclopentene [*142-29-0*], C_5H_8, M_r 68.12, is a colorless, pungent liquid. It is soluble in most organic solvents, including ethanol, diethyl ether, petroleum ether, and benzene. However, at 23 °C only 160 ppm of cyclopentene is soluble in water and 400 ppm of water is soluble in cyclopentene. Two typical organic azeotropes with cyclopentene are listed below:

Second component	*bp* (0.1 MPa), °C	Cyclopentene, mole fraction
Methanol	37	ca. 0.68
Methyl acetate	41.7	0.74

The physical properties of cyclopentene are listed in Table 3; thermal and thermodynamic properties are summarized in Table 4. The vapor pressure of cyclopentene (MPa) over the range 215 – 350 K is represented by

$$\log p = 3.6594 - 1482.13/T$$

Table 4. Thermal and thermodynamic properties of cyclopentene

∗ Ideal gas at 25 °C

Additional properties can be found in [6]. The IR [7], ^{1}H NMR [8], and mass spectra [9] of cyclopentene have been reported.

2.2. Chemical Properties

Cyclopentene undergoes the usual reactions of monoolefins, i.e., cycloadditions and additions to the double bond, substitutions in the allylic positions, and oxidative as well as metathetic cleavage of the ring system.

Cycloaddition reactions occur with allene [67] and butynone [68] in a [2 + 2] fashion and with conjugated dienes such as cyclopentadiene and 1,3-cyclohexadiene. Photochemically induced cycloadditions with aromatic substrates such as benzene [69] or toluene [70] occur by *meta* addition. Palladium-complex-catalyzed reaction of cyclopentene with dimethyl acetylenedicarboxylate results in a cocyclization reaction [71].

Addition reactions are numerous, such as hydrogenation to give cyclopentane, halogenations to give *trans*-1,2-dihalocyclopentanes, formylation to give formylcyclopentane, and hydrocarboxylation (Koch reaction) to give cyclopentanecarboxylic acid. Acid-catalyzed reactions with substituted benzenes lead to alkylation products, whereas the joint reaction of cyclopentene, benzene, and carbon monoxide leads to simultaneous alkylation and formylation to give 4-cyclopentylbenzaldehyde [72]. Epoxidation of cyclopentene has been carried out with peracids, hydrogen peroxide [73], [74], and oxygen by cooxidation with acetaldehyde [75]. Direct hydroxylation of cyclopentene to give 1,2-dihydroxycyclopentane has been achieved with modified permanganate [76] and with hydrogen peroxide – formic acid [77]. Cyclopentanone is obtained either by Pd-catalyzed oxidation with oxygen in a microemulsion [65], catalytically in the gas phase [78], or by catalytic hydration of cyclopentene and subsequent oxidative dehydrogenation of the intermediate cyclopentanol. Cyclopentanol can also be obtained by hydroboration of cyclopentene and subsequent oxidation [79]. Cyclopentene can be dimerized by homogeneous [80] and oligomerized by heterogeneous catalysis [81].

Substitution reactions occur predominantly in the allylic positions. Reactions with molecular oxygen lead to **26** as the primary product, both under autoxidation [82] and photooxidation [83]. Secondary reaction products are epoxides and alcohols [84]. Catalyzed photooxidations of cyclopentene lead to **27** [85] or **28** [86], depending on the catalyst used. Catalyzed cooxidation of cyclopentene and acetic acid affords **29** [87].

26

27

28

29

Ring cleavage and ring enlargement reactions occur under drastic oxidation or by metathesis. Ozonolysis in methanol can be guided by selective acid catalysis such that **30a** [88], **30b**, or **30c** [89] is formed. Catalyzed oxidations of cyclopentene with hydrogen peroxide and noncatalyzed oxidation with oxygen yield **30d** [90], and oxidation with nitric acid at elevated temperature and pressure gives **30e**. Oxidation of cyclopentene with oxygen on heterogeneous V_2O_5-based catalysts yields maleic anhydride [91], and with special catalysts, mixtures of maleic and phthalic anhydride result [92]. Heterogeneously catalyzed ammonoxidation yields pyridine and acyclic nitriles [93].

Metathesis of cyclopentene catalyzed homogeneously produces a polymer of structure **31**, called polypentenamer [40].

2.3. Production

Cyclopentene is formed in proportions of ca. 2.2 kg per ton of feed in the steam cracking of naphtha and is present in ca. 4 wt % in the C_5 fraction of pyrolysis gasoline [38], [39]. Such a low proportion is insufficient for industrial production, and hence, cyclopentene is effectively produced solely by selective hydrogenation of cyclopentadiene, generally by heterogeneous catalysis of gas-phase reactions with a wide variety of supported metal catalysts [94–99] or by heterogeneous [100–103] or homogeneous [104–106] catalysis of liquid-phase reactions. Feed materials are either crude dicyclopentadiene or the entire C_5 fraction.

Figure 3 shows the flow scheme of the Bayer process for the production of cyclopentene from crude dicyclopentadiene derived either from coal tar or steam-cracking operations (Section 1.3).

Crude dicyclopentadiene is monomerized in cracking column (a) at 170 – 190 °C, whereby codimers function as a diluent for the feed and are continuously removed from the bottom of column (a). Cyclopentadiene leaves the top of column (a), is mixed with hydrogen, and hydrogenated on a palladium catalyst [107] at 70 – 80 °C under moderate pressure in reactor (b). The effluent from (b) passes into (c), where it is separated into residual gas and liquid products. The liquid fraction passes flash column (d) to remove the major part of high-boiling components and is subsequently fractionated in column (e) to give cyclopentene. The yield of cyclopentene is 85 – 90 %, based on monomeric cyclopentadiene; the selectivity is 90 – 95 %.

Figure 4 shows the flow scheme of the NMP process for the production of cyclopentene from a C_5 fraction.

The C_5 fraction is introduced to reactor (a), where cyclopentadiene is thermally dimerized. In column (b) the remaining diolefins of the C_5 fraction (mostly isoprene and piperylene) and cyclopentene are selectively extracted with *N*-methylpyrrolidone (NMP). The raffinate is distilled in column (c) to give the lower boiling olefinic and paraffinic C_5 hydrocarbons as distillates and crude dicyclopentadiene as bottoms. Crude dicyclopentadiene is monomerized in cracking column (d) to give cyclopentadiene at the top and high boilers at the bottom. Subsequently, cyclopentadiene is mixed with hydrogen and selectively hydrogenated in reactor (e). In drum (f), the effluent from (e) is separated into residual gas and liquid crude cyclopentene. The latter is combined with the mixture of C_5 diolefins and cyclopentene obtained after extraction in column (b). The combined stream is processed by extractive distillation with NMP in column (g) to give piperylene at the bottom and a mixture of cyclopentene and isoprene at the top. This mixture is subsequently separated by fractional distillation in column (h).

This process allows the simultaneous production of isoprene and cyclopentene as well as the isolation of the cyclopentene present in the C_5 fraction.

Alternative modes of formation of cyclopentene are catalytic cyclization of piperylene [108], metathesis of 1,6-cyclodecadiene and polypentenamer, thermal isomerization of vinylcyclopropane, and pyrolysis of polymers [65].

2.4. Uses

Cyclopentene does not find substantial use in chemical syntheses. The broadest potential is offered by the production of polypentenamer, which has been tested extensively as an elastomer. Of potential use are also the methods for the selective oxidative cleavage of cyclopentene to give the various bifunctional products of structures **30a** – **30e**. Alkylcyclopentylbenzenes have low pour points and high flash points

Figure 3. Bayer process for the production of cyclopentene from crude dicyclopentadiene

and are useful as working fluids, and cyclopentylphenols have been tested as disinfectants, antioxidants, and light stabilizers for polymers. Polycyclopentene is used as a nucleating agent in the polymerization of propylene, whereby the properties of the resulting polypropylene are modified [109]. Epoxycyclopentanol (**28**) is of potential use for the synthesis of prostaglandins.

3. Toxicology

Among the three chemicals, acute toxicity increases in the order cyclopentene, cyclopentadiene, dicyclopentadiene. However, cyclopentene is most readily absorbed through the skin.

Cyclopentadiene forms a dimer spontaneously, and the reported toxicity probably is that for the dimeric form. The oral LD_{50} in rats is 0.82 g/kg [110]. The dermal LD_{50} in rabbits is 6.72 mL/kg [110]. Subcutaneous injection of 0.5 – 1 mL of cyclopentadiene monomer had no detectable effects on rabbits; 3 mL produced narcosis and fatal convulsions [111]. Mild kidney and liver damage occurred after exposure of rats to 500 ppm for 35 daily exposures each of 7 h [112]. No toxicological effects were observed in rats, guinea pigs, rabbits, or dogs exposed to 250 ppm for 135 d, 7 h/d [112]. Dogs exposed to 400 ppm cyclopentadiene for 39 d, 6 h/d, then to 800 ppm for 16 d, 6 h/d, showed no abnormalities in hematological parameters, liver function, serum enzyme levels, electrocardiogram, or microscopic appearance of tissues [112]. There is no evidence to suggest mutagenic, carcinogenic, or teratogenic potential of cyclopentadiene. The odor of cyclopentadiene at 250 ppm is unpleasant; thus, human workplace exposure limits have been placed below this level. The ACGIH has adopted a TLV value for cyclopentadiene of 75 ppm and an STEL limit of 150 ppm [113]. The MAK value is 75 ppm [114].

Dicyclopentadiene, the tricyclic form of cyclopentadiene, is the most toxic of the cycloolefin compounds described under this keyword. Oral and intraperitoneal LD_{50} values in rats are 0.35 mL/kg and 0.31 mL/kg, respectively. The dermal LD_{50} value for rabbits is 5.08 mL/kg [115]. Exposure of rats to saturated dicyclopentadiene vapor for 1 h produced 100 % mortality [115]. LC_{50} values for 4 h exposure to dicyclopentadiene vapor range from 146 ppm in mice to ca. 375 ppm in rats and 770 ppm in guinea pigs and rabbits [115]. Rats exposed to 0, 72, 146, and 332 ppm (7 h/d, 5 d/week, 10 d) exhibited treatment-related mortality only in the highest concentration group and no significant toxicological signs in the other groups [115]. Exposure to dicyclopentadiene at concentrations up to 74 ppm, 7 h/d, 5 d/week for 89 d, caused increased liver and kidney weights and renal tubular degeneration in male rats [115]. Dogs exposed to 0, 9, 23, and 32 ppm for 89 d showed no dose-related pathological changes and only minimal changes in serum enzyme levels [115]. Dicyclopentadiene is irritating to the eyes and respiratory tract of humans at concentrations as low as 1 ppm for 7 min. [115]. The olfactory threshold is ca. 0.003 ppm [112]. ACGIH has adopted a TLV of 5 ppm for dicyclopentadiene, but no STEL value has been proposed [113]. No MAK value has been adopted, but Soviet and Bulgarian workplace limits are 1 mg/m^3 or 0.185 ppm [114].

Cyclopentene is moderately toxic. In rats, the oral LD_{50} is 2.14 mL/kg [116], and the 4-h LC_{50} for cyclopentene vapor exceeds 8110 ppm [117]. However, concentrated vapors are lethal and exposure to 16 000 ppm for 4 h caused death in 4/6 rats [116]. Transdermal absorption occurs readily; the dermal LD_{50} in rabbits is 1.59 mL/kg [116]. Subacute exposure (6 h/d, 5 d/week, 3 weeks) of rats to 0, 870, and 3100 ppm cyclopentene vapor produced no toxicologically significant effects [117]. Chronic inhalation (6 h/d, 5 d/week, 12 weeks) of up to 1139 ppm did not result in hematological alterations, changes in serum chemistry, or organ pathology in rats [117]. Cyclopentene has not been suggested to be mutagenic or carcinogenic and reproductive hazards are unknown. No specific human toxicity attributed to cyclopentene has been described; however, headache and unpleasant sensations were reported by humans exposed to 32 ppm for 10 min. [117]. The threshold for detection of the odor of cyclopentene is ca. 13 ppm [117]. No MAK value for cyclopentene has been officially adopted [114]; however, values in the range 10 – 15 ppm are suggested based on subjective effects [117]. No TLV or STEL limits for cyclopentene are in effect currently in the United States [113].

These chemicals are listed in the U.S. Environmental Protection Agency's inventory for the TSCA [118]. Little is known about the hazards of chronic exposure; however, these chemicals are not presently listed as candidates for genetic toxicity or carcinogenicity testing by the U.S. Public Health Service [119].

Signs and symptoms of human intoxication with these cycloolefins include irritation of the eyes, nose, throat, and skin, excitation, loss of coordination and equilibrium, hypothermia, dyspnea, central nervous system depression, stupor, and coma [120]. Toxic and irritant properties and the possibility of dermal absorption suggest strongly that prudent handling practices, including adequate ventilation, protective clothing, neoprene gloves, chemical goggles, and respirators (self-contained, full face-mask, organic vapor cartridge) be used when working with these chemicals.

1. Introduction

In 1869, the French pharmacist HIPPOLYTE MEGE-MOURIEZ invented *olemargarine* as a substitute for butter; this was probably one of the earliest examples of an imitation dairy product [1]. *Margarine* was offered as a cheaper spread than butter, and almost 72 years passed before it was accepted as a food in its own right. In 1941 the FDA promulgated a federal standard for margarine [2], and in 1957 sales of 3.9 kg of margarine per capita surpassed the sales of butter [3].

During this growth period, the United States Congress passed the Filled Cheese Act of 1896 [4] and the Filled Milk Act of 1923 [5], which prohibited the development of substitute milk and cheese products. *Filled milk* (or *filled cheese*) is a substitute dairy product in which all or part of the butterfat is replaced with other fats or oils.

In the late 1940 s and the early 1950 s, sodium caseinate [*9005-46-3*], which was considered a chemical by the U.S. government, was found to be an excellent and inexpensive substitute for skim milk. The substitution of sodium caseinate opened the way for the development of imitation dairy products.

United States government actions, such as the repeal of the Filled Cheese Act and a federal court decision that the Filled Milk Act was unconstitutional, encouraged further development and marketing of imitation dairy products [6–8].

In 1987, there was no federal legal bars to the production or sale of imitation dairy products in the United States. Elsewhere in North America, the sale of some imitation dairy products is permitted in Mexico, but none are permitted in Canada.

The EEC countries allow the sale of nondairy coffee creamers and nondairy whipped toppings, provided they are not advertised as replacements of the dairy products simulated. There is concern in the EEC countries of the increasing sales of the nondairy products, and alternative choices for control are being considered by the Food and Drink Federation in the United Kingdom.

In Southeast Asia, canned imitation evaporated milk is legal in the Philippines, and imitation sweetened condensed milk is legal in Malaysia and Singapore.

2. Definition of Imitation Milk

The FDA defines a food as an imitation if it is a substitute for or resembles another food, but is nutritionally inferior to that food [9]. Nutritional inferiority includes any reduction in the content of an essential nutrient present in a measurable amount. A measurable amount per serving is 2 % or more of the recommended daily allowance [9], [10].

To paraphrase the FAO definition, an imitation milk product is prepared when one or more milk constituents have been replaced with other ingredients and the resulting food resembles the original product [11].

The term "imitation" refers to all simulated dairy products, except for nondairy creamer and nondairy whipped topping. Both were well-recognized market products prior to the estab-

lishment of the present FDA definition of an imitation food. These names, commonly used in the United States, are also used in this article.

3. Ingredients

Skim milk is the portion of milk that remains after milk fat has been removed by cream separation [12], [13]. Skim milk typically contains 90.8 wt % moisture, 3.41 wt % protein, 0.18 wt % fat, 4.85 wt % lactose [*63-42-3*], 0.76 wt % ash, and 0.12 wt %calcium, and 0.10 wt % phosphorus, as contained in the ash.

Nonfat dry milk is skim milk with only the fat and water removed. Standards in the United States and those proposed by the FAO [11] allow a maximum of 5 % moisture and less than 1 % fat [14].

Casein [*9000-71-9*] is prepared from skim milk by precipitation with acid at pH 4.6 or by the action of the enzyme rennin [*9001-98-3*] [15–19]. Edible dry casein is graded according to USDA standards as Extra or Standard [20].

Sodium Caseinate [*9005-46-3*] is made by solubilization of isoelectric casein with food-grade caustic soda and subsequent spray-drying. Caseinates are excellent food ingredients and are used in at least 26 food items [16].

Soy protein isolate is prepared from defatted soy flakes by separating and spray-drying the soluble protein fraction [21]. The dry isolate contains 90 – 95 % protein.

Whey protein concentrate made by ultrafiltration is a demineralized product rich in protein and with much of the lactose removed [22]. It has the advantage of being soluble over a pH range of 2 – 10 unless heated above 70 °C.

Vegetable fats constitute an important ingredient in imitation dairy products [23]. They contribute organoleptic properties such as richness and "mouthfeel," provide body or viscosity, play an important role in the air-incorporating capability (in whipped topping), increase whitening capacity (in nondairy creamers), and add tenderness (in imitation cheese).

The substitution of a vegetable fat for butterfat is complicated because available natural fats have fatty acid profiles which differ from that of butterfat [24–27]; see also → Fats and Fatty Oils. Fatty acids largely determine the physical properties of fats (triglycerides), which are esters of glycerol and fatty acids.

Table 1 compares the fatty acid composition of several functional vegetable fats with that of butterfat. Butterfat contains a variety of fatty acids, and some 70 % of them are saturated [24]. By contrast, domestic vegetable fats have fewer types of fatty acids, and these are of longer chain length, i.e., C_{16} and C_{18} and are saturated and unsaturated [25–27]. The unsaturated fatty acids listed in Table 1 are called palmitoleic and oleic if they have one unsaturated double bond; linoleic, if they have two; and linolenic, if they have three double bonds. Coconut fat, a lauric fat, contains approximately 95 % of a mixture of saturated fatty acids with short, intermediate, and long chain lengths. It is especially high in lauric acid [*143-07-7*] [25].

Every fat consists of a physical mixture of microscopic crystals of solid fat that holds the liquid oil. The *Solid Fat Index* (SFI) defines the ratio of solid fat to liquid oil at a given temperature. This measure indicates both the physical properties and the eating quality of a given fat [28]. The SFI is determined by dilatometry [28] and pulsed ^{1}H-NMR spectrometry [29].

According to the SFI profiles in Figure 1, the fat component of margarine (a) compares very closely with that of butterfat (b) [25], [30]; however, as shown in Table 1, it has a very different combination of fatty acids [24], [26]. Both have the moderate range of plasticity required for good spreadability at 25 °C [28]. By contrast, a hydrogenated coconut fat and hydrogenated palm kernel fat (lauric hard butter), as shown in Figure 1 by curves (c) and (d), respectively, contain relatively large amounts of solid fats [25], [31] at 15.5 – 21.1 °C and almost none at body temperature [25], [31]. The high content of solid fats in the fat mixture at room temperature adds body and firmness to the finished food and lessens the oil migration that causes greasiness. However, the rapid drop in the content of solid fat between room temperature and the final melting temperature in the mouth is responsible for the agreeable cooling effect of the product when tasted. These characteristics distinguish the lauric fats such as coconut and palm kernel oil from domestic oils and fats, and are preferred in whipped toppings and other imitation dairy products. Hard butters that closely resemble lauric fats, as shown by curve (e) in Figure 1, have been developed from domestic oil [32]. Be-

cause of their lower cost, these products are now used as substitutes for the substitutes.

Emulsifiers. The emulsifiers used in imitation dairy product formulations are esters of edible fatty acids of vegetable or animal origin and polyvalent alcohols such as glycerol [*56-81-5*], propylene glycol [*57-55-6*], and sorbitol [*50-70-4*] [33–38]. These emulsifiers may also be esterified with organic acids such as lactic, tartaric, and acetic acid or also reacted with ethylene oxide [35], [39–42]. Another group of emulsifiers is made by esterification of edible fatty acids with polyglycerols [43–46]. Lecithin [*8002-43-5*], a natural emulsifier, is extracted commercially from soybean oil [47], [48]. Many emulsifiers also contain small amounts of sodium or potassium salts of fatty acids, e.g., sodium oleate [*143-19-1*] [49].

Food emulsifiers reduce the surface tension of the oil – water interface; they adhere to the surface of the oil droplets and thus prevent their coalescence (see → Emulsions). Emulsifiers also stabilize the basic sodium caseinate – vegetable oil emulsion found in many imitation dairy products [50].

Carbohydrates. Carbohydrates are used as sweetening agents; they constitute a significant fraction of the total solids in imitation dairy products. The major sugars used are cane sugar and corn syrup solids at a sweetener level of 42 dextrose equivalents (DE). Corn syrup solids at DE levels of 20 – 25 are employed as carriers and encapsulating agents in spray-dried whip toppings and nondairy creamers [51]. Lactose [*63-42-3*] is used as an imitation ingredient for lactic acid fermentation, e.g., in imitation sour cream, salad dressings, and dips [52]. Whey is often used as a source of lactose.

Stabilizers. Colloidal polysaccharides (gums), such as carrageenan, locust bean gum, sodium alginate, guar gum, or carboxymethyl cellulose, thicken or increase viscosity [53–57]. Some polysaccharides have the following specific effects:

1) improvement of freeze – thaw stability, e.g., xanthan gum [*11138-66-2*] [58];
2) retardation of the growth of ice crystals, e.g., carboxymethyl cellulose [*9004-32-4*] or sodium alginate [*9005-38-3*] [55], [57];
3) prevention of syneresis, e.g., carboxymethyl cellulose, guar gum, xanthan gum, or microcrystalline cellulose [56–59];
4) stabilization of dispersions, e.g., cocoa powder (carrageenan [*9000-07-1*]) [53];
5) stabilization of oil-in-water emulsions, e.g., methyl cellulose [*9004-67-5*], hydroxypropyl methyl cellulose [*9004-65-3*], or hydroxypropyl cellulose [*9004-64-2*] [60–62]; and
6) improvement of cheese meltdown, e.g., locust bean gum [*9000-40-2*] [54].

Additives. Food-grade salt is used as a flavorant [63]. Food-grade disodium hydrogen phosphate [*7558-79-4*] and sodium citrate [*68-04-2*] are used as buffers for pH control in nondairy creamers and as emulsifiers in imitation cheese. Usage of flavors and coloring agents varies locally.

4. Manufacture

Imitation dairy products may be formulated with ingredients of dairy origin but are not limited to them. They resemble and substitute for dairy products. These products are processed largely with standard dairy equipment by using procedures similar to those of the dairy industry [64], [65]. Homogenization is used to disperse the fat uniformly and to control the size of the globule, which ranges from 1 to 3 μm in the finished emulsion.

Pasteurization can be carried out by either the batch or the vat method, or the high-temperature short-time method (HTST). Batch pasteurization is carried out at 63 °C for a minimum of 30 min. In practice, values of 71 °C for 30 min are used to adjust for higher fat and sugar levels. The HTST method is a continuous process that pasteurizes milk at a temperature of 74 °C for 15 s, although temperatures of 80 °C are not uncommon. This method can be substituted for the batch system of pasteurization in Figure 2. It is recommended when production exceeds 907 kg/h for a minimum of 3 h.

The manufacture of imitation dairy products involve a sequence of several consecutive but different unit operations, such as blending, or homogenization (Fig. 2). Only procedures that deviate from the common procedure illustrated in Figure 2, are described in detail when the various imitation dairy products are treated.

5. Products

Imitation Milk. Imitation milk is manufactured and sold in areas where fresh milk is unavailable, such as the islands of the Pacific Ocean, tropical areas of Latin America, Southeast Asia, and military installations. The source of protein is usually nonfat dry milk or, less frequently, fluid skim milk. Sodium caseinate may be used with concentrated whey protein and corn syrup solids at a DE of 42. Lauric- type fats, such as hydrogenated coconut or palm kernel fats, are generally used.

Imitation milk typically contains 3.25 % vegetable fat, 0.15 – 0.25 % mono- and diglycerides [66], 9 % nonfat dry milk solids, coloring agents, flavor ingredients, and vitamins, all in water. Imitation milk is made according to the basic procedure outlined in Figure 2; the homogenization pressure is 13.7 MPa in the first stage and 3.4 MPa in the second.

Soy Milk. Soy milk originated in the Orient two millenia ago and was introduced to the West around 1897 [67]. Soy milk is manufactured and sold in the Americas to religious groups, vegetarians, those (including infants) unable to consume cow's milk, and the general consuming public. If soy milk is sold in the United States, it must be labeled Imitation Soy Milk according to FDA standards; otherwise, the word "milk" must be avoided [68] and a new fanciful name used. Soy milk is prepared traditionally by grinding soaked soybeans with cold water, cooking them, and extracting the milk. A representative example contains 11.7 % solids, 3 – 3.2 % pro-

Figure 2. General processing steps for the manufacture of imitation dairy products
∗ except for sweetened condensed milk [80–90 °C; 0.5–2 min (HTST) or 10 min (batch)]

tein, 4.1 % oils or fat, 4.0 % sugars, and 0.4 % ash.

Imitation Sour Cream. Imitation sour cream is made from a simulated or imitation cream formulated of 17.5 % vegetable fat, 9 % nonfat milk solids, 0.5 % mono- and diglycerides, suitable coloring agents and flavor ingredients, all made up to 100 % with water.

The preparation process is carried out according to the basic procedure outlined in Figure 2; the homogenization pressure is 13.7 MPa in the first stage and 3.4 MPa in the second. Sour imitation cream is made by inoculating imitation cream at 22 °C with a starter culture and allowing the lactic acid flavor to develop. It is then packaged and allowed to set 24–28 h at 4.4 °C [64]. Direct acidification with lactic acid, citric acid, and other acids may also be used to make sour imitation cream, which circumvents the lengthy fermentation time, and assures a predictable flavor and product texture.

Dehydrated imitation sour cream is prepared by spray-drying with either a box-type or a tower spray dryer [65]. It is used as an ingredient in such convenience foods as dehydrated sauces and dehydrated liquid salad dressings [61].

Nondairy Creamers. Nondairy creamers are simulated creams used to whiten coffee. They have gained wide consumer acceptance because of lower price, convenience, and good shelf life. They are marketed in liquid, frozen, and powdered forms. The liquid form is used in small single-service containers where product turnover is rapid. The frozen variety has good shelf stability and is sold through retail and institutional channels. The dehydrated form has excellent shelf stability, does not require refrigeration, and is convenient to use. It is usually added directly to coffee in the powdered form, although it may be reconstituted.

Nondairy creamers must show good whitening power and be free of the defect called feath-

ering, or oiling-off, shown by the appearance of white coagulum on the surface of the coffee. Stabilizer salts (dipotassium hydrogen phosphate and sodium citrate) are essential to prevent feathering, which is caused by the pH of the water, the concentration of carbonates in the water, and the inherent acidity of coffee itself. Brews of roasted coffee vary in pH from 4.1 to 5.3, according to the area of origin. Per serving, well-stabilized nondairy creamer will raise the pH of coffee from 4.8 to 5.6, well above the coagulation pH of sodium caseinate (pH 4.6).

A typical liquid nondairy creamer contains 10.5 % corn syrup solids (25 DE), 10 % partially hydrogenated coconut oil or hydrogenated soy oil; 1.0 % sodium caseinate; 0.4 % emulsifier – a mixture of glycerol monostearate [*31566-31-1*] and distearate, sodium stearyl-2-lactylate [*25383-99-7*], and polyoxyethylene(20) sorbitan monostearate (Polysorbate 60); 0.10 – 0.15 % dipotassium hydrogen phosphate or disodium hydrogen phosphate; 0.1 – 0.2 % of a mixture of xanthan gum and guar gum; flavoring and coloring (β-carotene [*7235-40-7*]) agents as required; and water to 100 %.

Soy protein isolate can be substituted for sodium caseinate, and other emulsifiers, such as sorbitan monostearate and diacetyltartaric acid esters of monoglycerides, may be used.

Processing is outlined in Figure 2; the homogenization pressure is 13.7 MPa in the first stage and 3.4 MPa in the second. Homogenization is followed by cooling to 4.0 °C, and the product is packaged and stored at low temperature [64].

Frozen nondairy creamers are similar in formulation to the liquid form, except that greater attention is paid to the selection and concentration of the gums included.

Spray-Dried Nondairy Creamers. The basic ingredients are vegetable fat, emulsifier, protein (usually sodium caseinate), and a carbohydrate sweetener. The formulation of the powder is designed to provide sufficient fat to whiten the coffee when added in powdered form, and sufficient protein to encapsulate the oil during drying. The powder then flows freely and will not oil off in coffee. A typical spray-dried nondairy creamer contains 64.0 % corn syrup solids (25 DE), 25.75 % hydrogenated coconut or soybean oil, 4.0 % sodium caseinate, 1.3 % glycerol mono- or distearate, 2.0 % dipotassium hydrogen phosphate, 1.45 % anticaking agent (sodium silicoaluminate), 1.0 % moisture, and 0.25 % coloring and flavoring agents. This creamer is processed (as outlined in Fig. 2, except that the anticaking agent is withheld) by mixing the ingredients with water; the mix is adjusted to 45 % total solids at 60 °C, pasteurized at 71 °C for 30 min, homogenized at 13.7 MPa in the first stage and 3.4 MPa in the second, spray-dried in a vertical dryer, mixed with the anticaking agent, and agglomerated. Large particles improve the wettability of the powder in hot coffee [69], [70].

Evaporated Imitation Milk. Evaporated imitation milk is produced in the United States and in areas such as Southeast Asia. The formula used in the United States includes 6.0 % vegetable fat, 20 % skim milk solids (26 % total solids). The fats used are partially hydrogenated soy and cottonseed, and palm and coconut fats in the Asian area. Evaporated imitation milk is manufactured by the conventional method of water removal by vacuum pan evaporation [70] or by recombination of nonfat dry milk solids with water and vegetable fat to achieve the required solids level [71]. The addition of the proper amount of disodium hydrogen phosphate to the concentrated product before sterilization is essential to both processes.

In the *conventional method,* the fluid skim milk is prewarmed by passage through a single-pass tubular heater and concentrated in a vacuum pan. The concentrate is dropped, mixed with vegetable fat and calcium carrageenan, homogenized, standardized, treated with disodium hydrogen phosphate, fortified according to the local health code, packaged, and sterilized at 117 °C for 15 min or 137 °C for 2 min [65], [70], [72].

Evaporated imitation milk is manufactured largely by *recombination and reconstitution* as practiced in Southeast Asia, which precludes the need for an evaporation step. High-heat nonfat dry milk with a whey protein nitrogen index of 1.5 mg/g of nitrogen is recommended [71].

The procedure deviates from that shown in Figure 2, because after blending and filtration, the mix is preheated to 60 °C and homogenized in two stages at 14 MPa and 3.4 MPa. After homogenization, the viscosity of the prod-

uct is determined, the solids are adjusted, and monosodium and disodium hydrogen phosphate are added as required for stability. Furthermore the product is fortified with vitamins A and D as required by local code, canned, and sterilized (117 °C for 15 min) [71], [72].

Sweetened Condensed Imitation Milk. Sweetened condensed imitation milk is concentrated imitation milk preserved with a high concentration of sucrose. It has an excellent shelf life because the high osmotic pressure caused by the increased concentration of dissolved sugar inhibits the growth of microorganisms [70]. Sweetened condensed imitation milk is manufactured by vacuum pan concentration, to a limited extent, in Southeast Asia [73]. However, the trend has been toward recombination – reconstitution.

The selection of nonfat dry milk is important to avoid quality problems, such as excess viscosity in the finished product, especially on storage [74]. Pilot-scale evaluation of the effect of nonfat dry milk on the finished product is more important than the heat-treatment history of nonfat dry milk ingredients [75]. High grade crystalline sugar and partially hydrogenated lauric or palm fats are used.

Manufacturing procedures for sweetened condensed milk vary in formula, although two are used most frequently: (1) the U.S. Standard, which consists of 20 % nonfat solids, 8 % fat, 45.4 % sucrose with total solids of 73.4 %, and (2) the EEC formula, which consists of 22 % nonfat dry milk, 9 % fat, 43.5 % sucrose with total solids of 74.5 %. The order of mixing ingredients is important because nonfat dry milk must be hydrated before sugar is added. The mixing system is critical because high shearing is necessary to hydrate the product in the very viscous mixture of nonfat dry milk and crystalline sugar in a very limited amount of water; the Cowles dissolver is generally used [76], [77]. To expedite the solubilizing of nonfat dry milk, a small excess (ca. 10 %) of water is added and subsequently removed.

The process differs in some details from the procedure outlined in Figure 2. Thus, the dry ingredients are dissolved sequentially in water at 50 – 60 °C, first the nonfat dry milk, and then the sugar. The dry milk must be dissolved completely before the sugar is added. The fat is added last. The blend is filtered, homogenized in a single stage within a pressure range of 3.5 – 6.8 MPa, pasteurized at 80 – 90 °C for 0.5 – 2 min (HTST) or 10 min (batch), flashed into a large vacuum cooler under aseptic conditions, where it is cooled to 25 – 30 °C, seeded with sterile lactose, filled, and canned. Flash cooling removes the excess water [77].

Nondairy Whipped Toppings. Nondairy whipped toppings are prepared as oil-in-water emulsions. They contain the basic ingredients fat, protein, sucrose, corn syrup solids, stabilizer, and emulsifiers. Protein-less topping is an exception; it contains a cellulose derivative in place of protein. These ingredients in liquid toppings are used in the following proportions: 15 – 35 % vegetable fat, 1 – 6 % protein, 6 – 12 % sucrose, 2 – 20 % corn syrup solids, 0.1 – 0.7 % stabilizer, 0.4 – 4.0 % emulsifier, salt, and flavoring and coloring agents and water as needed.

A formulation for a simple nondairy liquid whip topping at a moderate fat level consists of 25.6 % partially hydrogenated coconut oil, 6.8 % sucrose, 2.3 % sodium caseinate, 0.7 % lactic acid ester of glycerol monopalmitate, 0.30 % sodium stearyl-2-lactylate (SSL), 0.12 % Polysorbate 60, 0.073 % sodium alginate, 0.05 % dipotassium hydrogen phosphate, and water to 100 %.

The preparation of the emulsion follows the general procedure illustrated in Figure 2, except that homogenization is carried out in two stages at a pressure of 10.3 MPa in the first stage and 3.4 MPa in the second. After homogenization, quick cooling of the emulsion is important to induce rapid fat crystallization.

These toppings are manufactured and marketed in several different forms. Nondairy liquid toppings are distributed as refrigerated items to food processors such as bakeries, confectioneries, ice cream manufacturers, and restaurants. Distributed initially in small milk cans on a returnable basis, products are now sold in 1-Gallon (3.79-L) gable top paper milk cartons. These toppings are also available in the concentrated and frozen forms.

Other emulsifiers used in formulating nondairy liquid whip toppings are, for example, lecithin, polyglycerol esters of fatty acids, and hydroxypropyl cellulose which is used as a substitute for a protein stabilizer. This cellulose in-

gredient and other related cellulose derivatives are often added to liquid whips that are to be sold in the frozen state.

Well accepted as a whipped topping, *ultrapasteurized aerosol nondairy topping* is packed under pressurized nitrous oxide gas in strong metal containers fitted with a product release valve. When released, the pressurized gas forces the liquid topping through the valve, creating the whip as it expands through the nozzle.

Ultrapasteurization, according to the Public Health Service of the FDA, means that such products must have been thermally processed at or above 138 °C for at least 2 s, either before or after packaging, to produce a product which has an extended shelf life under refrigeration [66]. The ultrapasteurized mix is processed outside the can, cooled to 4 °C, canned, capped, and charged with nitrous oxide gas.

Spray-dried whip topping was developed in the 1950 s and early 1960 s. This form of topping is reconstituted by the consumer with cool water, milk, or skim milk, and mechanically whipped in a few minutes [78], [79]. It has excellent foam stiffness and aeration. The powder product is very stable.

An example of a spray-dried topping is formulated to contain 45 % partially hydrogenated coconut fat or palm kernel fat, 10 % lactic acid ester of monopalmitate, 8 % sodium caseinate, 26 % corn syrup solids (25 DE), 10 % cane sugar, 0.06 % sodium alginate, and 0.94 % moisture. The mixture is adjusted to 45 % total solids or higher, processed as outlined in Figure 2, homogenized in two stages at 10.3 MPa and 3.4 MPa, spray-dried under pressure atomization into a vertical dryer or box dryer, cooled to 7 – 13 °C, tempered (i.e., stored to dissipate the heat of crystallization), dry-blended with additional sugar and flavoring as required, and packaged.

Other lipophilic emulsifiers that perform well in dehydrated whip toppings are propylene glycol monostearate and acetylated monoglycerides.

Protein-less nondairy whip topping is prepared by substituting methyl cellulose, hydroxypropyl methyl cellulose, or hydroxypropyl cellulose for sodium caseinate or soy protein isolate. These ingredients form stable films around fat globules and are acid-stable. These properties have been utilized in developing stable toppings made with acidic fruits [80], [81].

Prewhipped frozen toppings are the most popular form marketed in the United States. Prewhipped by the manufacturer, they are sold in the frozen form and usually packed in round, widemouthed plastic containers. They are ready to be used upon thawing.

One method of manufacture consists of pumping the homogenized emulsion, at a temperature of 2 – 6 °C, through a rotary whipping machine and on to a filling machine. After packaging, the product is quickly frozen to – 29 °C.

Imitation Cheese. Two types of imitation cheese are manufactured in the United States. One is made with casein, vegetable fat, and water. The other is made with skim milk and vegetable fat, and then fermented. The ingredients required are skim milk or nonfat milk, acid or rennet casein (preferably rennet), partially hydrogenated soybean oil, salt, a coloring agent, and disodium hydrogen phosphate. The flavors used are prepared by lipase and protease hydrolysis of cheese trimmings.

Imitation cheese made with casein and vegetable fat is prepared by mixing 27 % casein and 25 % fat with salt, disodium hydrogen phosphate, flavoring, coloring, and water to bring the total to 100 %. The mix is plasticized at a temperature range of 82 – 92 °C in an auger-screw cooker heated by steam injection [82]. After being cooked, the imitation cheese is extruded, and packaged. The pH of imitation cheese is adjusted to 5.6 – 5.8 for improved texture and stringiness when heated.

Imitation cheese made with skim milk and vegetable fat utilizes conventional cheese-making techniques. Imitation milk is prepared by processing skim milk and vegetable fat as described in Figure 2. The milk, at 22 °C, is inoculated with 2 – 5 % lactic starter culture, which is kept at 22 °C until the curd is set at pH 4.6. The curd is then cut, cooked, and finished to the required degree by adding hydrolyzed cheese flavor (→ Cheese, Processed Cheese, and Whey). Imitation cheese produced by fermentation is usually made into processed imitation cheese. Imitation casein vegetable fat cheese is used primarily to manufacture imitation mozzarella.

6. Standards and Quality Control

Sanitary quality standards are regulated by sanitary codes at the state and local levels in the United States. However, the United States has no federal standards of identity for imitation dairy products, except for margarine [83] and mellorine [84], previously considered imitation dairy products but now accepted as standard foods. Analytical procedures for quality control of ingredients and finished imitation dairy products are published by several trade associations [72], [85], [86] and technical societies [87], [88].

7. Nutrition

The use of imitation dairy products should not be viewed as a potential nutritional hazard, unless they are substituted indiscriminately in infant formulas [89]. However, proper labeling and suitable levels of nutritional equivalence should be observed for fluid imitation milk. A nutritional study of imitation milks carried out on monkeys and rats showed no differences in overall appearance, milk intake, and body weight compared to those fed cow's milk [90]. A review of nutritional studies of coconut oil suggests that some negative findings are consequences of abnormal nutrition, rather than inherent defects in coconut oil [91]. Coconut oil and palm kernel oil are the two most important lauric oils. Epidemiological studies of atherosclerosis in populations consuming large amounts of coconut oil are cited to show that coconut oil in a natural diet is not disadvantageous and may even be of advantage.

A nutritional study of severely malnourished infants indicated that "milks based on a high quality ISP (isolated soy protein) appropriately enriched with D,L-methionine are the practical equivalent of the best modified cow's milk products as the main or only source of protein in the diet of rapidly growing infants and small children" [92–96].

A review from 1983 contains recommendations for and against soy protein formulas with regard to infant feeding [97].

8. Toxicology

Most additives used in the food industry in the United States are considered GRAS (generally recognized as safe) by the FDA [98]. The FDA has set maximum usage limits on a few food emulsifiers used in nondairy creamers and nondairy whipped toppings [99]. The highest limited amount of emulsifier is 0.4 wt %; the lowest, 0.3 wt %, based on the finished product. The FAO – WHO has published a list of ADI (acceptable daily intake) values in which 16 emulsifiers are compared [33], [103]. The highest listed ADI value is 50, the lowest is $0-2.5\,\mathrm{mg\,kg^{-1}d^{-1}}$. Other ingredients with ADI imposed limits by FAO – WHO are xanthan gum with a limit of $10\,\mathrm{mg\,kg^{-1}d^{-1}}$, as well as several food colors whose highest limit is $0-25\,\mathrm{mg\,kg^{-1}d^{-1}}$ and lowest is $0-0.1\,\mathrm{mg\,kg^{-1}d^{-1}}$ [100], [101].

9. Economic Aspects

The difference in cost between butterfat and vegetable fat has provided a major incentive for the development of imitation dairy products. For example, in early 1986 butterfat was six times as costly as hydrogenated coconut fat. Sales of imitation dairy products in the United States amounted to about 628×10^6 \$ in supermarket retail sales for 1985. Whipped and frozen toppings and powdered nondairy creamers account for more than three-quarters of these sales [102].

For the period 1980 – 1984 sales of both frozen nondairy toppings and frozen nondairy creamers rose slightly; all other categories declined (no data are available for imitation cheese).

1. Introduction

Dental materials are used for the replacement of destroyed or lost structures (hard tooth substance, teeth, soft tissues of the mouth, tissues of the head) and for the restoration of disturbed functions (masticatory, phonetic, esthetic, physiognomic) of the orofacial organ. They are involved in the morphological, physiological, and psychological reconstitution of the patient (curative effect). At the same time they prevent structural decay and functional failure (preventive effect). Their use takes into account biological and technical aspects. This is documented by the large number of international standards (ISO). There is a requirement for chemical biocompatibility (lack of toxicity, allergenicity, mutagenicity, cancerogenicity), functional biocompatibility (strength, environmental resistance), and technical functionality (handling, ergonomics, economy). Some dental materials are incorporated permanently or temporarily in the orofacial organ; legally, they are similar to medicinal products. Other materials are used for the production of tooth restorations and do not come into contact with the patient's tissues. From the standpoint of industrial hygiene they must be completely harmless to the user (dentist, dental technician, dental assistant).

There are may uses for dental materials:

- Reconstruction of decayed tooth structure (enamel, dentin) by fillings and crowns
- Replacement of missing teeth by partial or full dentures
- Surgical prostheses and epitheses in orofacial prosthetics

Some dental materials are primarily used for preventive purposes (sealants for developmental pits and grooves in the biting surfaces of teeth and athletic mouth guards to reduce forces applied to teeth during contact sports).

According to their handling dental material can be grouped in the following way:

- Direct restorative materials, which are processed in the mouth
- Indirect restorative materials, which are fabricated outside the mouth

1.1. Direct Materials

Pure Gold. Gold foil can be formed into solid gold of nearly theoretical density by mechanically condensing it directly into a retentive cavity preparation. By means of small-diameter condenser tips, the gold is work-hardened to have properties comparable to a 90 % gold – 10 % copper cast alloy. Electrolytically produced powdered gold containing 0.5 % calcium may be substituted for gold foil. These restorations have low mechanical properties and are restricted to small non-stress-bearing applications in posterior teeth because of aesthetics.

Silver Amalgam. Silver amalgam is supplied as a powder consisting mainly of silver, with a balancing amount of tin, copper, and minor elements. These amalgams are classified as low-copper (< 6 %) and high-copper (13 – 30 %) types. The powder is mixed with mercury to form a plastic mass which is condensed into a retentive cavity preparation. The surface

is carved shortly after placement; depending on the product, the surface may be finished and polished immediately or at a second appointment. Amalgam is used in posterior teeth because of its gray appearance and is successful in stress-bearing restorations. In badly decayed teeth, amalgam may be retained by threaded metallic pins placed into dentin, which extend into the amalgam. It can be used to build up the crown of a tooth (a core) on which a cast restoration is placed.

Polymers and Composites. Difunctional oligomers and monomers, usually mixed with fillers, are used to fill developmental pits and fissures in the occlusal surfaces of enamel to prevent caries. Before placement, the enamel is etched with acid, rinsed, and dried. Etching provides for mechanical retention of the sealant. The sealants are formulated to be polymerized in situ by a chemical-activated or light-activated free-radical mechanism. The treatment is most successful on the teeth of children soon after eruption.

Anterior teeth with small to moderate fractures or decay can be restored with composites. They contain an inorganic filler of various particle sizes, as well as difunctional acrylate oligomers and monomers. Composites are today only rarely available as two pastes for the chemically activated type and mostly as a single paste for the light-activated type. After cavity preparation, an adhesive is applied on enamel and dentin and polymerized. The peripheral enamel is etched with acid, rinsed, and dried. Equal volumes of the chemically activated type are mixed, syringed or packed into the preparation, and allowed to polymerize. For the light-activated type, the paste is placed into the cavity preparation and polymerized by exposure to light. Setting occurs promptly, and final finishing to proper contour is done. When the proper shade is used, the boundary between the restoration and the tooth is difficult to detect.

Cervical caries or eroded areas of teeth are generally restored with glass ionomers. They consist of a powder and a liquid (an acid-soluble glass and an aqueous solution of polyacrylic acids). The exposed dentin is cleaned, and an adhesive is applied. Any peripheral enamel is etched with acid. The components are spatulated to a thick paste and packed into the prepared area. Leached metal ions from the powder and the polymer acid react; a similar reaction may occur between the calcium from the tooth and the polymer acid to form an adhesive bond. Finishing is delayed for 24 h because of the slow completion of the reaction. This method is most successful for cervical restoration; its functions are to restore the contour of the tooth, thus increasing periodontal health, and to reduce the sensitivity of the tooth.

Composites have been used in posterior teeth, but the lack of wear resistance has restricted their application to situations in which aesthetics is essential. Composites with higher filler content and wear resistance have been developed, and restoration of posterior teeth with composites has increased.

Agents are available to bond enamel and dentin with composites. The bonding agents are organic compounds with a variety of functional groups. They are applied to the cavity preparation before the composite, but the adhesive bond is weak.

Composites are used as cores in severely broken-down teeth and, in combination with the acid-etch technique, as veneers on severely discolored or deformed anterior teeth.

Cements. Cements are classed as *luting cements* (attaching a cast gold restoration to a tooth) or *base cements* (support for an amalgam restoration). Chemically, they are classified as (1) zinc phosphate, (2) zinc oxide – eugenol and modifications, (3) zinc polyacrylate, (4) glass ionomer, or (5) resin and composite cements. The applications of cements are listed in Table 1.

Zinc phosphate cement is supplied as a powder (mainly ZnO) and a liquid (mainly H_3PO_4 in water). The ratio of powder to liquid is higher for a base than for a luting cement. The acid – base reaction is exothermic, and the cement is mixed on a cool glass slab to control the temperature. The mix is then placed on the restoration and tooth, and the excess is forced out when the restoration is seated. A base cement is stiffer and is packed into the bottom of the cavity preparation and contoured. It is acidic when placed, and the pulp is protected with a varnish on the dentin. Cements have low thermal conductivity and high stiffness and strength; they provide thermal insulation for the pulp and mechanical support for

the restoration. Zinc phosphate cement can also serve as a temporary restoration while a permanent restoration is being made.

Table 1. Applications of cement types

Cement type	Applications
Zinc phosphate	retention of restorations and orthodontic bands; high-strength bases; temporary restorations
Zinc oxide – eugenol	temporary and permanent retention of restorations; low- and high-strength bases; temporary restorations; root canal sealers; gingival surgical tissue pack
Zinc polyacrylate	retention of restorations and orthodontic bands; temporary restorations; high-strength bases
Glass ionomer	retention of restorations
Resin and composite	retention of crowns, bridges, and orthodontic brackets; retention of acid-etched bridges

Zinc oxide – eugenol (ZOE) cements have a variety of applications (Table 1). Unmodified ZOE consists of a powder or paste (mainly ZnO) and a liquid or second paste (mainly eugenol). No significant heat is produced during the mixing or the formation of the chelate, zinc eugenolate. Unmodified ZOE has low strength and is used in a thin layer as a liner, as a root canal sealer (to fill a root when the pulp has been extirpated), or as a surgical pack for areas around the teeth where gingival tissue has been removed for periodontal reasons. The cement has an obtundent effect on the pulp.

Polymers added to ZOE improve its strength and allow it to be used for temporary restorations or for the temporary retention of crowns and bridges. When 2-ethoxybenzoic acid is substituted for part of the eugenol and alumina is added, a high-strength cement results that can be used for permanent cementation.

Zinc polyacrylate cements are usually powders (mainly ZnO) and liquids (mainly aqueous solutions of copolymers of acrylic acid). They are spatulated, with thin mixes used to retain restorations or orthodontic bands, and thick mixes used as bases. Although the mixes are acidic, they have a much smaller effect on the pulp than phosphoric acid.

Glass ionomer cements are powders (acid-soluble glass containing high levels of fluorine) and liquids (aqueous solution of acrylic acid copolymers). They are spatulated, and the cementing consistency is used to retain cast metal restorations. The cement sets promptly, but the chemical reaction is completed slowly and the cement margin should be protected with varnish from saliva for a day.

Resin cements are powders (acrylic polymers and sometimes fillers) and liquids (acrylic monomers), whereas *composite cements* are usually two pastes containing diacrylate oligomers, diacrylate monomers, fillers, and polymerization initiator systems. They are used for the retention of crowns and bridges. In combination with the etching of enamel, these cements are used to attach orthodontic brackets to teeth without bands. The acrylic cements are better with plastic brackets, whereas the resin composites are better for metal brackets. The latter are also used to attach bridges to acid-etched enamel and acid-etched base metals.

Liners. When dental decay in dentin extends near or to the pulp, a liner is needed. If a thin layer of sound dentin exists, a paste – paste zinc oxide – eugenol liner is used as an obtundent and to protect the pulp. If decay extends to the pulp, a calcium hydroxide liner is needed to stimulate the deposition of reparative dentin in the area of exposure. The calcium hydroxide materials are usually supplied as two pastes which are mixed together and set by the reaction of a disalicylate and calcium. Liners are used in thin layers, have very low strengths, and have therapeutic value. High-strength bases are placed on top of them to give mechanical support.

Varnish. Dilute solutions of natural or synthetic polymers in organic solvents are used as varnishes. They form a thin plastic film over freshly cut dentin and reduce the diffusion of material components into the tubules to the pulp.

1.2. Indirect Materials

Cast Restorations. Alloy classes are gold – copper, palladium – silver, nickel – chromium, cobalt – chromium, and cobalt – chromium – nickel. They are fabricated by the lost-wax method: a wax or plastic pattern of the restoration is placed in a refractory investment (see Sec-

tion Auxiliary Materials). After the investment has hardened, it is heated to remove the wax and to expand the mold. Molten alloy is forced into the space occupied by the pattern, usually by centrifugal force. The investment and metal are then cooled, and the restoration is finished.

Gold casting alloys are of types 1 to 4 with increasing copper and other non-noble metal content. Type 1 is soft and used for non-stress-bearing restorations; type 2 is stronger and used for simple posterior stress-bearing restorations; type 3 is still harder and stronger, and is used for complex posterior crown and bridge restorations; and type 4, the strongest, can be used in removable partial dentures. Types 3 and 4 contain enough copper for their as-cast hardness to be increased by heat treatment.

The price of gold has increased the use of palladium – silver, cobalt – chromium, and nickel – chromium alloys for crowns and bridges. They are generally harder and stronger than type 3 gold alloys. They have higher melting points than gold alloys and must be cast in high-temperature investments.

Removable partial denture frameworks are almost always cast from nickel – chromium, cobalt – chromium or cobalt – chromium – nickel alloys because of their lower cost and higher stiffness (about twice that of gold alloys). Partial denture frameworks are so large that free-standing patterns distort during investing. Patterns are formed on refractory investment models of the upper or lower teeth. The pattern and the model are then invested to produce the mold used in the casting process. Plastic base and artificial teeth (Section Auxiliary Materials) are attached to the framework to produce the denture. These alloys have higher melting points and hardness, and lower density, than gold alloys and are more difficult to finish.

Wrought Metals. Wrought wires of 18 – 8 stainless steel, cobalt – chromium – nickel, nickel – titanium, and titanium – molybdenum are used in orthodontics in biomechanical devices to move teeth by the application of forces. After treatment, these appliances are removed. The stiffness of 18 – 8 stainless steel and cobalt – chromium – nickel is the highest, followed by titanium – molybdenum and then nickel – titanium. Fabrication of the appliances often involves soldering or spot-welding, which must be done carefully so that minimal damage to the wrought metal occurs.

Stainless steel is also employed in the manufacture of small tapered files and reamers used to clean out the root canals of infected teeth during endodontic treatment.

Preformed wrought shell crowns of stainless steel, nickel – chromium, or tin- and aluminum-based alloys are used for semipermanent and temporary restoration of children's primary teeth. They are supplied in a multitude of sizes for different teeth. The best size is selected, trimmed, and adapted to the correct shape. It is then cemented with a permanent or temporary cement.

Feldspathic, aluminous, and *crystallizable* glass ceramics are used for the preparation of full anterior crowns. In the first two, the crowns are built up on a die of the prepared tooth covered with platinum foil. Ceramic powder is mixed with water, and the slurry is painted on the matrix. Water is removed by vibration, blotting, baking, and firing. The crown is built up initially with more opaque ceramics; then more translucent ceramics are used toward the surface. Characterization results in a restoration that matches the appearance of natural teeth. Aluminous ceramics have alumina added to the feldspar to improve resistance to fracture.

Ceramic crowns are retained with a dental cement. Because they are brittle and lack high strength, ceramic crowns are used mainly on anterior teeth where appearance is primary.

Ceramics are used to manufacture artificial teeth for dentures. These teeth are held in position by acrylic polymers and by mechanical retention of pins in anterior, and diatoric holes in posterior, teeth. The teeth are available in a variety of shades, sizes, types, and shapes.

Ceramics and Metal – Ceramic Combinations. A thin metal coping is cast to fit the tooth. Special ceramics that bond to the metal are applied to the outside surface. The completed crown has a strong metallic substructure covered with an aesthetic outer layer. These combinations have superior strength compared to ceramic restorations and can be used for posterior as well as anterior crowns and bridges.

Metals that have been used are gold-, nickel-, and palladium-based alloys. Feldspathic ceramics with matching thermal expansion properties

are essential. They are also retained in the mouth with dental cements.

Full ceramic crowns and small bridges can be made using press ceramics. In this process a ceramic pellet is heated to a soft stage and pressed into a form inside of an investment material similar to casting a metal crown. The material is a glass ceramic reinforced by leucite crystals.

Another way to produce full ceramic crowns and small bridges is to use aluminum oxide or an aluminum oxide/zirconium oxide ceramic to build up the crown on a refractory die, loosely sinter it so that it does not shrink, and infiltrate it with a glass. For a more toothlike appearance it must be veneered with a veneering ceramic like a metal framework.

CAD/CAM techniques can also be used to prepare full ceramic restorations. When this technique is used to prepare frameworks from aluminum oxide or yttrium-stabilized zirconium oxide, even wide-span bridges can be made out of full ceramic. The framework must be veneered with a veneering ceramic which has a thermal expansion coefficient that fits to the framework. Since milling of a framework out of densely sintered zirconium oxide ceramic is time-consuming, a computer technique is used to precalculate sinter shrinkage and produce an enlarged framework out of presintered material. The enlarged framework is then dense sintered to a fitting framework.

Ceramics are today only rarely used to manufacture artificial teeth for dentures. These teeth are held in position by acrylic polymers and by mechanical retention of pins in anterior, and diatoric holes in posterior, teeth. The teeth are available in a variety of shades, sizes, types, and shapes.

Polymers. Acrylic polymers and copolymers are used for partial and complete denture bases, soft and hard denture liners, artificial denture teeth, crown and bridge facings, and temporary materials. They are usually processed by a dough-molding technique, and free-radical polymerization is initiated either by heat or by a chemical. Shrinkage is controlled by mixing three parts of polymer and one part of monomer (usually methyl methacrylate) to form a dough. The mixture is packed or pressed into a sectional mold formed by the lost-wax technique. The mold is formed by investing a denture where the artificial teeth are supported by a wax denture base. Pressure is maintained on the mold until the monomer has polymerized. The flask is then removed from the appliance and the plastic base is finished. A pour processing technique is sometimes used, in which a mixture of polymer and monomer is poured into the sectional mold.

The tissue-bearing surface of a denture may be made of a soft polymer such as plasticized acrylic or a silicone rubber for patients who have special problems wearing dentures.

The facial surfaces of anterior metallic crown copings may be coated with tooth-colored acrylics for aesthetic reasons. The polymer is mixed or delivered as a paste with diacrylate monomers having a low vapor pressure. They can be processed in an oven or cured by light or microwaves without investing because of the low volatility of the monomers. Acrylic denture teeth are also manufactured by means of dough molding. They are available in a wide range of shades, types, and geometries. They are softer and less wear resistant than ceramic teeth but can be chemically bonded to the acrylic denture base. Temporary restorations are made directly in the mouth from polymer – monomer mixes, with the aid of an impression. They are then retained with a temporary cement until the permanent restoration is made.

Athletic mouth protectors are made by forming in a vacuum, a sheet (3 mm) of polyethylene – poly(vinyl acetate) copolymer over a model of the athlete's upper teeth. After cooling, the excess is cut away with scissors and the edges are flame-polished. When worn, these protectors nearly eliminate oral injuries in contact sports.

1.3. Auxiliary Materials

Impression Materials. Since diagnostic and therapeutic measures in the oral cavity are restricted, a working model must be created outside the mouth. This is done by physically transferring information from the patient to the dental laboratory by a two-step inversion process:

1) Impression taking: a plastic material is brought into contact with the object to be reproduced and removed as an impression (negative) after hardening by cooling or chemical reaction
2) Model production: the impression is filled with a die material to give a model (positive)

The model must correspond to the shape and dimensions of the morphological situation in the mouth and, if necessary, give an instantaneous picture of functional sequences. Impression and die materials form an integrated whole. For the application of the impression material to the object to be reproduced, rigid impression trays are necessary. They are available prefabricated from metal or resin or custom made in the dental laboratory from light-polymerizable filler-containing polymers (composite materials).

Models and Dies. Models and dies are usually made from one of three types of gypsum material and, less frequently, from plastics (usually epoxy) and metals (electroformed silver or copper). Gypsum materials are compatible with all impression materials, whereas epoxies are compatible with some rubber impressions. Dental compound and addition silicones are compatible with copper forming, whereas most rubbers are compatible with silver forming.

Plaster, stone, and *improved stone gypsum* products are supplied as powders that are mixed with water to a heavy slurry which is vibrated into impressions. The strength, accuracy, and cost increase from plaster to improved stone.

Epoxy materials are supplied as an epoxide paste and a liquid amine catalyst. The fluid mix is poured into the rubber impression. They set slowly compared to gypsum materials.

Electroforming of rubber impressions is done by painting the impression with finely divided metal powder; this surface is then made the cathode in an electroplating system. Pure copper or silver is used as the anode, and electroforming is carried out by using the appropriate electrolyte and direct current (d.c.). Plating is continued until more than 1 mm has been deposited; the remaining space is then filled with acrylic plastic or improved stone.

Pattern Materials. Patterns to be used in the lost-wax technique are most often made from wax and occasionally from acrylic plastics, supplied as a powder and a liquid. Inlay, crown, and bridge patterns are made from harder waxes which are built up in increments on the model or die. Accurate wax patterns are possible when the thermal expansion and stress relaxation properties of the wax are taken into consideration. Denture bases are prepared from softer waxes, which keep the artificial teeth in the correct relationship before the base is invested and processed in acrylic plastic.

Dental Casting. The lost-wax technique in combination with centrifugal casting is the most common way to make dental castings. The free-standing wax pattern or the wax pattern on a refractory investment model is invested in a ring by using gypsum-, phosphate-, or silicate-bonded investment. The latter two are used with high-melting alloys. In addition to the binder, the investment consists of silica materials. It is mixed with water or special liquids and poured around the pattern in the ring. After setting, the wax or plastic pattern is burned out (480 – 980 °C, depending on the technique). The alloy is melted and then cast into the mold. The shrinkage of the wax pattern during mold formation and of the alloy on cooling is compensated for by careful control of the setting and thermal expansion of the investment.

2. Metals

2.1. Introduction

Metals and alloys are widely used materials in modern dentistry. In restorative dentistry metallic materials are used for fillings for periodontal and endodontic treatment; prosthetic dentistry uses metals for crowns and bridges, partial dentures and implant suprastructures; and for orthodontic treatment, the elastic and shape-memory effects of metals and alloys are utilized. Finally in dental implantology, titanium metal is almost exclusively used for its osseointegration capabilities.

Depending on the specific application, the required physical properties and processing characteristics vary widely. For instance, an amalgam filling material must first be a plastic mass, which allows the dentist to pack it into the dental cavity; it must then harden so that the filling can be contoured with a sharp instrument shortly after placement; finally, it must harden rapidly, so the patient can chew an hour or two after the filling has been placed. Root canal posts and implants must be made of rigid, strong materials with a high elastic limit. They are mostly prefabricated because of requirements for precision, surface properties, and strength. Other requirements for certain applications (indications) may

be a certain coefficient of thermal expansion or melting range if the metal framework is to be veneered with a tooth-colored ceramic material.

General requirements for all dental materials result from the requirements to be met by a finished dental restoration in the oral cavity and from interactions with the biological and chemical processes of the patient. The quality of the restoration, which ultimately guarantees long-term success in the mouth, is determined not only by the material but also by the quality of its dental and technical processing. These three areas — medicine, processing technology, and materials science — cannot be regarded independently of each other.

The most important medical requirements on dental alloys are:

- Corrosion and tarnish resistance in the mouth
- Biocompatibility
- Esthetics

No material should be introduced into the oral cavity that can corrode under the sometimes-aggressive conditions that prevail there, that is, dissolve with the formation of considerable amounts of metal ions. Tarnished layers, which can develop by the reaction of metal ions with constituents of the saliva, are also undesirable because they lead to esthetically unsatisfactory results.

The requirement for a good biocompatibility of a material is closely related with the requirement for corrosion resistance. This means that materials which come into contact with the body of the processor or of the patient must not cause any harm to health. When a new alloy is formulated, a high corrosion resistance must be ensured, which in addition to the composition can be improved further by a homogeneous, fine-grain microstructure. An appropriate processing procedure in the laboratory also plays an important role here. However, since even highly corrosion resistant alloys release minimal amounts of ions into solution, elements that have a proven high allergenic or toxic potential, such as Cd, Be, Pb, and Ni, must not be used.

2.2. Metallic Materials for Fillings

2.2.1. Pure Gold

In the past, the filling of tooth cavities by cold-weldable pure gold was rather popular. Today this technique is less important, because it is time consuming and inconvenient to the patient.

Gold for fillings is available in different shapes: gold foil of 1 μm thickness or rolled into cylinders (Gold Cylinder, Williams Gold Ltd.); electrolytically deposited mat gold in strips partially wrapped in gold foil; and gold powder encased in gold foil (Williams Gold Ltd.); partially sintered chemically deposited gold powder [12, 13]. One type contains a small addition of calcium to improve work hardening (Electraloy RV, Williams Gold Ltd.). The pieces must be annealed and allowed to cool; they are then inserted immediately into the cavity and condensed by malleting with hand instruments or electric condensers [13]. Direct plastic gold fillings are advisable only for small cavities on the occlusal surfaces or near the neck of the tooth. Larger fillings with two or more surfaces must be made by the inlay casting technique.

2.2.2. Silver Amalgams

Amalgams are alloys of mercury with other metals. Silver amalgams were introduced to dentistry at the beginning of the last century. The dentist mixes an alloy powder with mercury to obtain a plastic mass. This plastic amalgam is then packed into the prepared tooth cavity. It begins to harden after a few minutes; the surface can be shaped by carving after 10 min or less; and after 1 – 2 d, the amalgam is completely hardened, and can be polished.

Properties. Today many different types of alloys are available for amalgams. They consist of finely divided Ag – Sn – Cu alloys, sometimes with small additions of zinc, mercury, indium, or noble metals. They are distinguished by the following criteria

Silver content:	>65 % or 40 – 60 %
Copper content:	10 – 30 % or <6 %
Grain size:	<150 μm or <60 μm
Shape:	cut filings or atomized spherical particles
Number of alloys:	single alloy or particles from different alloys

Until around 1970, only alloys with high silver content and low copper content were used. These conventional alloys mainly consist of the intermetallic phase Ag_3Sn (γ), which reacts with mercury to form two new intermetallic phases (γ_1 and γ_2):

$$Ag_3Sn\,(\gamma) + Hg \rightarrow Ag_3Hg_4\,(\gamma_1) + Sn_8Hg\,(\gamma_2) + Ag_3Sn$$

An excess of Ag_3Sn remains in the hardened amalgam; its γ_2 phase is the weakest and most prone to corrosion. Corrosion products are tin oxides and tin oxide chlorides. The mercury from the corroding γ_2 phase diffuses back into the amalgam and causes mercuroscopic expansion [14] which damages the margins of the filling.

Since 1965, alloys with higher copper content have been developed. Instead of Sn_8Hg, the mercury-free phase Cu_6Sn_5 (η') is formed, which is less prone to corrosion; it has the additional advantage of making the matrix phase Ag_3Hg_4 more creep resistant.

The first amalgams that were free of the γ_2 phase were the dispersion-type alloys, which contain about 30 % of spheres (< 35 µm) of the Ag – Cu eutectic (28 % Cu) in addition to the conventional Ag_3Sn filings [15]. The initial reaction with mercury is similar to that of the conventional alloys, which is followed by

$$Sn_8Hg + Ag/Cu \rightarrow Cu_6Sn_5 + Ag_3Hg_4$$

This diffusion-controlled reaction takes place within 1 – 7 d.

Atomized alloys consisting of Ag_3Sn and Cu_3Sn with an extremely fine duplex structure were later developed to eliminate the γ_2 phase in dental amalgams. The silver content is 40 – 60 %, and the copper content 13 – 29 % [16, 17]. The reaction with mercury is:

$$Ag_3Sn/Cu_3Sn + Hg \rightarrow Ag_3Hg_4 + Cu_6Sn_5$$

An excess of unchanged particles remains in the completely hardened amalgam. The non-gamma-2 amalgams with higher copper content yield much more stable margins and brighter polished fillings than the conventional low-copper amalgams.

Some of the cut alloys are preamalgamated to accelerate the wetting and reaction with mercury. For this purpose, the alloy powder is treated with a mercury salt solution, which precipitates mercury at the surface of the particles. Zinc is also added as a deoxidizer; it slightly increases the strength of the amalgam but, if contaminated with moisture, has the disadvantage of producing hydrogen, which causes delayed expansion or blisters.

Production. Filings are produced by cutting annealed ingots of alloy (10 – 20 kg) in a machine with a rotating milling cylinder and water cooling. They are ground, sieved, annealed under protective gas, etched with acid or preamalgamated (see above), rinsed, and dried (Fig. 1).

Figure 1. Remission electron microscopy (REM) photograph of Luxalloy-non-gamma 2

Spherical alloy particles are produced directly from the melt by pouring it through a hole in the bottom of the crucible and atomizing the melt stream with high-pressure nitrogen. The atomized droplets solidify while falling or are quenched in water, forming small spheres or irregular particles. The powder is sieved and annealed in a reducing atmosphere or etched with acid.

Cut filings or atomized particles are either used as a single-alloy powder or mixed according to different manufacturing prescriptions. By annealing, the rate of reaction with mercury (setting time, working time for the dentist) and the setting expansion of the alloy can be influenced and optimized.

Standards. Amalgams were the first dental materials to be standardized. The following international standards exist: ISO 24234 (Den-

tistry – Mercury and Alloys for Dental Amalgam).

Handling. In earlier times, the alloy powder and mercury were mixed in a glass mortar with pestle. Today, electric mixing devices produce the amalgam paste in 6 – 30 s. The recommended ratio of mercury to alloy depends on the type of particles. The range is 0.9 – 1.2:1, with less mercury used for spherical powders and more for filings. An excess is expressed by the dentist during compression into the cavity. Ratio, mixing frequency, and mixing time influence the properties of the amalgam before and after hardening. A low ratio causes a dry amalgam paste and porosities in the filling. An extended mixing time may change the setting expansion into a contraction.

Toxicology and Occupational Health. The mercury release from amalgam into water or saliva was found to be very low: 2.4 – 3.8 $\mu g/cm^2$ during the first day from fresh amalgam and 0.1 – 0.3 $\mu g/cm^3$ per day from completely hardened amalgam. Tooth brushing twice a day increases this amount to 0.5 – 0.8 $\mu g/cm^2$ per day. The daily uptake of mercury from normal food is 7 – 12 µg, and can be as high as 40 – 50 µg with one meal of fish [18]. The daily dose from amalgam fillings is below 10 µg [80].

Spilled mercury and amalgam waste can be a source of mercury vapor and therefore hazardous for the dentist and his staff. Spillage must be avoided by using modern dispensing and mixing devices, and by keeping wastes in closed boxes under thiosulfate solution. By this means, the mercury concentration in dental offices can be kept below 10 $\mu g/m^3$. The TLV and MAK of mercury are 50 and 100 $\mu g/m^3$, respectively.

In the mouth, a protective layer of saliva suppresses the evaporation of mercury. The uptake of mercury by breathing through the mouth was found to be less than 0.1 $\mu g/m^3$ for an amalgam surface of 1 cm^2 [19]. Contact between amalgam fillings and gold restorations in the mouth should be avoided, because the different potentials of these materials can lead to the following disadvantages: elevated corrosion, discoloration, and metallic taste. Allergic reactions to mercury in amalgam fillings are observed only in very rare cases.

2.2.3. Copper Amalgams

In former times, copper amalgams were used in childrens' temporary teeth. They were supplied in the form of tablets with about 35 % copper and 65 % mercury. They had to be plasticized by heating above 128 °C, and they hardened on cooling to form the phase Cu_7Hg_6 [20]. The heating process is a dangerous source of mercury vapor. The corrosion resistance of copper amalgams is poor.

2.2.4. Gallium Alloys

Gallium has a melting temperature of 30 °C. A eutectic alloy with indium and tin is liquid at room temperature and can be used to form a paste similar to the amalgam paste. When it is mixed with an alloy similar in composition to an amalgam alloy with silver, copper and tin and in one case 9 % palladium, it hardens in the same way. Since the vapor pressure of liquid gallium at mouth temperature is close to that of solid iron at this temperature, evaporation of gallium is of no concern.

The problem with this type of filling material is that gallium is not as noble as mercury. This means corrosion rates are higher than those for amalgam. The alloy tends to undergo dark discoloration in the mouth and the corrosion rate of gallium from this type of alloy is two orders of magnitude higher than that of mercury from amalgam. Therefore biocompatibility of this type of alloy is by no means better than that of amalgam.

2.3. Metallic Materials for Prosthetic Restorations

The wide span of qualities required in materials for restorative devices has led to a variety of metallic dental materials. Castings are used for rebuilding partly damaged teeth (inlays, onlays, crowns) and for replacing missing teeth (bridges, partial dentures). Cast fillings, crowns, and bridges are permanently fixed to the tooth or abutment with a dental cement; removable partial dentures are usually held in position by clasps or telescoping parts attached to the adjacent teeth. Prefabricated precision attachments

are also used as interlocking devices for the reversible fixation of partial dentures. Brazing is the most commonly used technique when metallic parts of a dental restoration must be joined, but other techniques, such as laser welding, are becoming increasingly popular.

To achieve a lifelike appearance of the artificial dentures, tooth-colored polymeric and ceramic coatings (veneers) are applied to the metal substructure. Depending on the veneering material and the technique of application, the substrate alloys must have very specific properties. Since the ceramic veneer is fired onto the metallic dental framework, alloys suitable for this technique must fulfill specific requirements concerning thermal expansion, melting range, and bonding characteristics to the ceramic material. Alloys for this porcelainfused-to-metal technique are usually referred to as PFM alloys or simply porcelain alloys. Metallic dental restorations are usually manufactured by a specific dental casting technique. Other means of manufacturing inlays, crowns, and bridges are milling, sintering, or electroforming [81 – 83].

2.3.1. Precious Metal Casting Alloys

Due to their high corrosion resistance, precious metals are well suited for use in the oral cavity, where the metals come in contact with saliva, which contains hydrogen ions H^+ (pH value of up to 3) and oxygen.

A measure for the stability of a metal is its electrochemical standard potential (relative to the standard hydrogen electrode):

Al	– 1.7	Co	– 0.3
Ti	– 1.6	Cu	+ 0.4
Zn	– 0.8	Hg	+ 0.8
Cr	– 07	Ag	+ 0.8
Fe	– 0.4	Pd	+ 1.0
Ni	– 0.3	Au	+ 1.4

The more positive the potential, the more corrosion-resistant the element. Due to their very high values, precious metals are not attacked by hydrogen ions. As shown in Figure 2, the high electrochemical potential of gold and palladium is retained in binary alloys provided the Au or Pd content exceeds 50 atom % in all phases of the alloy.

Figure 2. Corrosion resistance of binary gold and palladium alloys

Gold has a melting point of 1063 °C and a coefficient of thermal expansion of ca. 14.6×10^{-6} K^{-1} and therefore offers ideal properties as a dental material. The warm yellow color is highly esteemed due to its positive influence on the esthetics in the oral cavity. The platinum group metals all have a significantly higher melting point, so that, with the exception of palladium, none of these elements can be considered as a base for dental alloys.

In comparison with gold, palladium has a lower density and a lower price, so that material costs for restorations with palladium-base alloys are considerably lower. Palladium, however, is white. Since the coefficient of thermal expansion and melting point are outside the range required for ceramic alloys, considerable amounts of alloying elements have to be used to meet the requirement profile for PFM alloys.

Platinum is used as alloying element, especially in high-gold alloys, to increase the strength and to raise the melting point. Ruthenium and iridium are used as additives for grain refinement.

Tables 2 and 3 give an overview of the various base systems used as dental alloys with their main alloying elements. A differentiation is made between alloys suitable for ceramic veneering (PFM alloys) and alloys mainly used for unveneered restorations or for veneering with dental acrylics (C + B alloys).

High-Gold Alloys. Alloys on the base of Au – Ag – Cu have been used for the manufacturing of dental restorations since the introduction of the casting technique. The Au – Ag – Cu ternary system is shown in Figure 3. While a complete miscibility of the components is possible in the

Table 2. Composition of typical precious metal dental alloys

Alloy	Composition, wt %

* Coefficient of thermal expansion

Au – Cu and Au – Ag systems over the entire range of concentration, the solubility of silver in copper and of copper in silver is only limited. With decreasing temperature, this solubility gap increasingly extends in the direction of the gold corner. Alloys with a composition in the range of the solubility gap can be hardened by heat treatment [86]. During this process, precipitates that are rich in copper or silver are formed and increase the hardness and strength of the alloy. Figure 4 shows the structure of the Degulor M alloy in the soft and hardened condition.

By means of slight variations in the silver and copper contents, the extent of precipitate and thus the mechanical properties of these alloys can be varied. Consequently, it is possible to design optimum alloys for the various clinical indications. A further improvement of these alloys is achieved by adding platinum and iridium. Due to the grain-refining effect of these elements, dendritic solidification and thus an inhomogeneous element concentration within the grain (segregation) can be avoided. The fine-grain microstructure also leads to an improved corrosion and tarnish resistance; ductility and strength are increased. Table 2 lists the composition and Table 3 the properties of Degulor alloys for various indications, together with a selection of other DeguDent alloys.

* Coefficient of thermal expansion

based on poly(methyl methacrylate) (PMMA) to give the restoration a tooth-colored appearance. Esthetically higher grade restorations, however, could only be obtained by veneering with ceramic materials that are fused to the alloy at ca. 980 °C. Since the solidus temperature of the alloys based on Au – Ag – Cu lies below this temperature, these alloys could not be used for this purpose. Newly developed low-fusing (hydrothermal) ceramic materials allow for ceramic veneering of this type of alloys.

Since the difference between the firing temperature of the ceramic and the solidus temperature of the alloy should be at least 100 °C, the solidus temperature of such an alloy must be raised above the melting point of gold (1063 °C). Therefore, platinum and palladium are used as alloying elements (Fig. 5). However, the addition is limited by the requirement for a maximum liquidus temperature of 1300 °C.

Figure 4. Microstructure of Degulor M in the hardened and soft states
A) Hardened, soft + 15 min/400 °C/air; B) Soft, 15 min/750 °C/Ar, H_2O

Figure 5. Ternary Au – Pt – Pd phase diagram with isotherms of the solubility gap and some liquidus temperatures

Palladium as an alloying element can be used very effectively to raise the melting range because, in contrast to platinum, it widens the melting range considerably less. A very wide melting range increases the tendency to develop segregations during solidification of the alloy. However, because of the unlimited miscibility of Au and Pd only a solid-solution hardening is possible that does not result in an adequate strength of these alloys. Moreover, palladium adversely affects the gold color. In contrast, platinum permits precipitate hardening at Pt contents exceeding about 6 wt % (Fig. 5) [87]. Therefore, palladium, which raises the melting range, and platinum, which increases the melting range and hardenability, are usually added to high-gold PFM alloys. Moreover, since alloys with high strength are required, especially for long-span bridges, nonprecious metals such as copper, tin, indium, iron, etc. are added to these alloys in concentrations up to 2 wt %. Since in systems with such complex structures and properties a theoretical description with phase diagrams is not possible, the development of dental alloys usually requires considerable experimentation with different alloy formulations. Results of such development efforts are often reflected in patents [88 – 90].

Alloying elements such as tin, indium, iron, etc., efficiently harden high-gold PFM alloys but they also lower the melting range. For compensation, palladium is added. Due to the decolorizing effect of palladium, gold-base high-strength ceramic alloys are therefore nearly white. Table 3 lists the properties of high-gold Degudent alloys. Aside from increasing the strength, the nonprecious metals are significant for a good bond between alloy and veneering ceramics. During oxidation and veneering, these additives are oxidized near and at the surface and support the wetting of the alloy by the glass phase of the dental ceramics [91].

The development of new low-fusing dental ceramic materials such as Duceragold (firing temperature ca. 740 – 780°C) made it possible for the first time to develop a golden-yellow, high-strength alloy (Degunorm) which is suitable even for large-span bridges and partial dentures. Degunorm and Duceragold have been marketed as the Golden Gate System since 1993. The alloy is mainly derived from Degulor M, which has been known since the mid-1950s. By lowering the Cu content to 4.4 % and removing the Pd the veneering characteristics and color were optimized (see Tables 2 and 3).

Gold-Reduced Alloys. With the sharp increase of the gold price in 1982, high-gold alloys became increasingly unaffordable for many patients and for health insurance systems, leading to an increased consumption and development of alloys with a reduced gold content. The Au – Ag – Cu alloy base is similar to that of high-gold alloys but the gold content is reduced to ca. 60 % and the silver content is increased by more than 20 %. The palladium content is ca. 5 %. Due to the low atomic weight of palladium

compared with gold, it can replace almost twice the amount of gold and platinum in these alloys, so that the corrosion resistance is also ensured. Due to their Pd and lower gold content these alloys no longer display the intensive yellow color of the Degulor group alloys. Typical examples are the Stabilor alloys (Tables 2 and 3).

Improper handling of these alloys can lead to porosities on the surface of dental castings. These porosities can lead to the formation of so-called aeration elements. Due to the different oxygen contents on the surface of the alloy and inside the shrinkage cavities, a difference in the electrochemical potential results between the two areas. In copper-containing alloys, copper ions go into solution inside the pore, migrate out of the pore, and react with anions in the saliva to form a dark discoloration around the shrinkage cavity (tarnish).

This potential problem provided the impetus for the development of copper-free, gold-base alloys, based on the ternary system Au – Ag – Pd. In contrast to the Au – Ag – Cu system, however, all binary systems and the ternary system have no miscibility gaps. Precipitate hardening is therefore not possible.

The ternary system Au – Pd – In has a solubility gap like the binary-edge systems Au – In and Pd – In. It should therefore be possible to achieve an increase in strength by alloying an adequate amount of indium to the Au – Pd – Ag base. The range of the solid solution of In in this ternary basis is the narrowest at medium gold contents, so that only little indium has to be alloyed to obtain precipitate hardening.

The C & B alloys are not suitable for ceramic veneering. Since there was also a demand for economical alloys for ceramic veneering, it was necessary to reduce the platinum content in addition to the gold content. Therefore, Au – Pd was chosen as the base system. To achieve a noticeable cost reduction, the gold content was reduced to 50 – 60 % and the palladium content was raised to 35 – 40 %. Due to the strong decolorizing effect of palladium all these alloys are white.

The high proportion of palladium results in a considerable rise of the melting range to values far above 1400 °C. To lower the melting range, elements such as indium, zinc, tin and to a slight extent also gallium have to be alloyed to considerably lower the melting range. At the same time the severe lattice distortions introduced by these alloying elements cause strong solid-solution hardening. A typical product is Deva 4 (Tables 2 and 3). The high precious metal content of this alloy (ca. 90 wt %) ensures good corrosion resistance in the mouth. The higher content of nonprecious elements in comparison with high-gold alloys, however, can make these alloys more sensitive to processing errors.

Palladium Alloys. Attempts to develop low-gold (or even gold-free) precious metal dental alloys date back to the 1930s, where following the depression Ag – Pd alloys were introduced as dental casting alloys. When manufactured properly, dental restorations made from these alloys show reasonable clinical behavior, but a slight darkening may occur over time as a result of the high silver content of these alloys and the tendency of silver to tarnish if it comes into contact with sulfur. Silver-base alloys that contain up to 5 % gold are still widely used, e.g., Palliag M (see Tables 2 and 3).

In the field of PFM alloys the development of low-gold Pd alloys dates back to the early 1970s, when Pd – Ag alloys were first introduced for veneering with dental ceramics. However, due to the tendency of Ag-containing alloys to frequently cause greenish discolorations in the dental ceramic materials available at that time, a higher acceptance of Pd alloys for ceramic veneering came only when first Ag-free versions were developed in the late 1970s as a response to soaring gold prices and with the introduction of nongreening ceramic in the early 1980s (e.g., Duceram).

To obtain Pd-base alloys suitable for dental ceramic veneering materials and for melting and casting with standard laboratory equipment the melting range of palladium has to be lowered by at least 250 °C, while the coefficient of thermal expansion has to be increased to a minimum of $14.0 \times 10^{-6}\,K^{-1}$. For this purpose, low-melting metals are used for alloying. The element with the strongest influence in lowering the melting temperature is gallium (Fig. 6). Tin, copper, and cobalt also lower the melting temperature significantly, whereas indium and silver have only a minor effect. Silver, copper and cobalt are completely soluble in palladium, whereas gallium, tin, and indium have solubility limits in palla-

dium of 10, 17, and 18 wt %, respectively, at 700 °C [92].

Figure 6. Influence of various metals on the liquidus temperature of binary Pd alloys

In contrast to high-gold alloys, in which a finely dispersed second phase with a high content of precious metal is required to increase the strength, second phases are undesired in palladium-base alloys. To obtain a single-phase alloy, the amount of gallium and copper have to be reduced distinctly (Fig. 7). The ternary phase diagram shows that with decreasing copper content the area of the solid solution crystal also becomes wider, but even outside the two-phase region the formation of a second phase is possible as a result of additional alloying elements. A further reduction in the risk of undesired segregation and the formation of second phases can be achieved by grain refinement.

Palladium and silver, similar to palladium and copper, are completely miscible. Silver, however, can be alloyed to a high degree since it does not lead to any formation of oxide during the firing of veneering ceramics. Typical Pd – Ag alloys contain ca. 30 wt % silver. As additional alloying elements, tin, indium, and zinc are preferably used to provide the required mechanical characteristics and CTE values by solid-solution and precipitate hardening. They also lower the melting range.

At 1000 °C silver has a vapor pressure of ca. 100 mbar. During the firing of ceramic materials, which is performed under vacuum (about 50 mbar), silver evaporates from the surface of the alloy and is partly deposited on the surface of the ceramic, often resulting in a greenish discoloration. New types of ceramics which are insensitive to discoloration by silver have been developed (e.g., Duceram).

2.3.2. Nonprecious Metal Casting Alloys

Nickel-Base Alloys. Although Co – Cr and Ni – Cr alloys with adequate tarnish and corrosion resistance have been available since about 1930, noble-metal alloys are still the materials of choice for cast inlays, crowns, and bridges. Efforts to fuse dental ceramics to nonprecious alloys were first successful only around 1970, when Ni – Cr alloys were used that are similar to creep- and sag-resistant superalloys for high-temperature applications such as furnaces and

Figure 7. Ternary phase diagram Pd – Cu – Ga

turbines. Chromium forms a passive layer on these alloys, which prevents further corrosion. The basic composition is usually 80 % nickel and 20 % chromium. Specific additives (e.g., Mo, Nb, Ta, and Al) are necessary to obtain the desired properties and control carbide formation. Manganese provides sulfidation resistance, while boron and silicon lower the melting range, and beryllium improves castability as well as the alloy – ceramic bond.

Advantages of CFM alloys based on the Ni – Cr system are the low density, lower thermal conductivity, the high yield strength, and the modulus of elasticity, which is almost twice that of precious metal alloys. However, the handling of these tough alloys is not as easy as that of precious metal alloys, and high-temperature laboratory equipment is required for processing on a consistently successful basis. The technical procedure is extremely sensitive, and technicians must be specially trained. Common problems include miscasts, poor fit, porcelain fracture, weak joints when brazed after ceramic firing, and extended finishing time.

The biocompatibility of nickel alloys is another point of concern. Nickel can cause allergic dermatitis. Therefore, the use of nickel-containing alloys is contraindicated in nickel-sensitive patients. Technicians must also be aware of this potential risk. Moreover, nickel dust is considered a carcinogen. Cancer of the respiratory tract has been particularly well documented in persons who are occupationally exposed to nickel; therefore, precautions must be taken to avoid inhalation of nickel dust during processing. Beryllium is of concern mainly to the dental technician because it may provoke beryllosis.

Cobalt-Base Alloys. Primarily because of the hazards associated with nickel and beryllium, alloys have been developed that do not contain these elements. The Co – Cr – Mo casting alloys used for removable dentures (Section 2.3.3) are not useful for the CFM technique, because they are not scale resistant, their oxides react unfavorably with the ceramic veneer, and their thermal expansion does not match that of the common brands of dental ceramics. Special alloys have been developed to overcome these problems. Some Co – Cr alloys are on the market, with tungsten instead of molybdenum as a main constituent or with titanium partially replacing chromium. The latter alloys are especially prone to severe oxidation at elevated temperature and must be melted and cast under vacuum. Strength, melting range, and thermal expansion of these Co – Cr CFM alloys are higher than those of the Ni – Cr alloys. A completely modified processing technique is necessary to obtain acceptable results [5 – 7].

Titanium and Titanium Alloys. Formerly, titanium and titanium alloys were only used for implants, but pure titanium has become increasingly popular as casting alloy. Advantages of titanium are biocompatibility, low density, and low thermal conductivity. A disadvantage is that titanium undergoes a phase transformation during cooling from solidification temperature to room temperature. The high-temperature α-phase is stabilized by impurities, especially oxygen. Contamination of the surface creates a brittle surface layer called α-case. Since titanium is a very reactive metal it must be cast under an atmosphere with a very low oxygen content, and the investment material must be chemically more stable than for other dental castings. The low density is not only an advantage but also a disadvantage, since higher casting forces are required to obtain void-free castings. In this context the low X-ray opacity of titanium is an advantage because radiographs can be used to determine whether the casting is free of voids.

Recently, ceramic materials for veneering titanium have been introduced into the market (e.g., Duceratin). Clinical observations have indicated that titanium veneered with these dental ceramic materials still has a higher risk of fracture and failure of the metal – ceramic bond. [81, 84]. However, acrylic resin veneers give better results on titanium than on precious-metal or other nonprecious-metal dental alloys [85].

2.3.3. Casting Alloys for Removable Dentures

Removable partial dentures are commonly cast of suitable alloys, whereas complete dentures are now rarely made of metal; for orthodontic appliances, wires made of stainless steel or nickel – titanium alloys are generally used. The removable partial denture, which is primarily

Table 4. Composition of typical base metal dental alloys

supported by the mucosa, is usually held in position by clasps around the remaining natural teeth. The clasps and the denture base are often cast simultaneously as one piece of a single alloy by using a specific investment casting technique. Co – Cr alloys are mainly used for this purpose (e.g., Biosil F; Tables 4 and 5). Esthetically more pleasing devices to attach a removable partial denture to natural teeth or to a fixed partial denture are telescoping crowns or industrially prefabricated attachments (see Section 2.6).

2.4. Brazing Alloys

Brazing, commonly called soldering in the dental profession, is the operation most extensively used in dental laboratories for joining two pieces of a metallic dental appliance together. Spot welding is used occasionally, and laser welding is becoming increasingly popular.

Brazing alloys are used in the form of strips, rods, or ingots. Brazing is frequently conducted in electrical furnaces or by means of a gas – oxygen torch between 750 and 1150 °C. A brazing flux dissolves or removes oxide and has a positive effect in promoting rapid wetting and spreading of the brazing filler metal. Because brazing must be conducted at temperatures that are 20 – 150°C above the liquidus temperature of the filler metal without fusing the parent metal, a suitable brazing alloy has to be chosen for the particular combination of metals to be joined.

Noble-Metal Alloys. Because brazed joints must be corrosion resistant in the oral environment, noble-metal alloys are the filler materials of choice. Brazing alloys based on the Au – Ag – Cu system are called *gold solders*. They usually contain 50 – 75 % gold, up to 10 % platinum group metals, balance silver and copper, plus up to 15 % zinc and, occasionally, minor additions of indium or tin to lower the melting range. These yellow-colored gold solders are suitable for all joining purposes in the fabrication of fixed restorations, except for joining prior to firing the ceramic veneer. For this application, high-melting Au – Ag alloys are used, which contain 60 – 80 % gold and up to 10 % platinum metals, but only trace amounts of base metals.

When the joint should not differ in color from white parent alloys, *Au – Pd – Ag brazing al-*

loys are available. Although they contain up to 45 % copper, zinc, tin, and indium, some of these have acceptable corrosion resistance if the noble metal content is not less than 40 %. These white brazing alloys are preferred in the fabrication of orthodontic appliances, removable partial dentures, and ceramic-veneered restorations made of base-metal casting alloys.

Brazing alloys of Ag – Cu – Zn, sometimes used for joints in removable appliances, cannot be accepted for long-term use, because of their low corrosion resistance. Furthermore, the brazing operation itself reduces the passivation of some base-metal parent alloys, which can result in mechanical breakdown of the appliance because of corrosion of the joint.

Alloys of Au – Ni with about 80 % gold, are used particularly for direct brazing of a clasp wire to denture bases cast from Co – Cr alloy. Fusion of a high-melting *Au – Ni brazing alloy* to one part of a restoration made of a base-metal alloy, prior to brazing it with a gold solder to another part made of a noble-metal alloy [1, 3, 4], is also common.

Base-Metal Alloys. So far the only base-metal brazing alloys commonly used in joining base-metal CFM alloys prior to firing the ceramic veneer are Ni – Cr – Si – B alloys, e.g., BNi74CrFeSiB 980 – 1080 (ISO 3677 designation for nickel-based solder containing 14 % Cr, 4.54 % Fe, 4.5 % Si, 13 % B, and having a working range of 980 – 1080 °C).

2.5. Metallic Materials for Implants

Since the early 1970s alloplastic implants have become increasingly important. They are used as replacements for missing teeth and for retaining full dentures. All implant materials must be highly corrosion resistant in the oral cavity as well as in the bone structure. They must also be strong enough to withstand mastication forces. Implants are either supported by the jaw bone (subperiosteal implants) or fixed in the jaw bone (endo-osseous and endodontic implants). *Subperiosteal implants* are fabricated, according to an impression of the jaw bone, in a dental laboratory by using the lost-wax method with a Co – Cr – Mo casting alloy. Individually shaped implant frameworks are obtained, which allow a prosthesis to be fixed on the posts passing through the gum. Nowadays this kind of implant is not very popular anymore because of problems with the fixation of the implant on the bone.

For *endo-osseous and endodontic* (transfixation) implants, prefabricated parts of various alloys are available from the dental industry. They are fixed in the jawbone. Titanium and titanium-based alloys are most important because of their favorable chemical and physical properties and their excellent biocompatibility (e.g., Ti with 6 % Al and 4 % V, or Ti with 5 % Al and 2.5 % Fe). Tantalum is also highly biocompatible, but because of its high density and poor mechanical properties, it is not yet used as an implant material on a wide basis. Wrought cobalt-based alloys, such as Co – Cr – W – Ni and Co – Ni – Cr – Mo, have also been used as implant materials. Formerly, stainless steel with ca. 18 % Cr, 14 % Ni, and 3 % Mo was used as implant material, but its corrosion resistance and hence its biocompatibility are not as good as of other alloys [8].

Good incorporation of implants into the jaw bone requires a rough surface, while the surface of the transmucosal part has to be smooth. Roughening of the surface is done by spray coating of titanium with titanium or by sandblasting or etching. The difficulty in all-cases is to keep the surface free from foreign material which may reduce biocompatibility.

To enhance the healing process and to provide a bioactive surface some implants are provided with a surface layer of hydroxyapatite or similar calcium phosphate compounds. The problem with these layers is that the adherence to the metal surface is too weak to withstand the shear forces during the insertion process. Chipped-off parts from the surface may create problems during the healing process.

Implants are also available completely made from ceramic material, mainly aluminum oxide, or from carbon glass or carbon fiber. The disadvantage of the carbon implants is the black color, which is visible through the gum.

A survey of materials approved in general implant surgery is given in the ISO Standard Series 5832.

Implant systems are most successful when prefabricated endodontic and endo-osseous implants are provided along with the corresponding root canal and bone-cutting instruments, respectively.

Because of the different techniques of placing implants, various shapes of implants are available. Blades, screws, and hollow cylinders are used mainly for endo-osseous implants [9, 10]. After a root resection, endodontic implants must be inserted through the root canal into the jawbone. The usual implant shapes are therefore limited to needles, pins, and screws [11].

2.6. Metals and Alloys for Other Purposes

For other applications and operations in dentistry besides casting and brazing, metals and alloys are used in the form of either prefabricated parts or semifinished materials.

Root Canal Posts. Because of the severely corrosive conditions in crevices, highly corrosion-resistant materials must be used for root canal posts which are inserted into the root of a nonvital tooth as a retention for the artificial die. Some prefabricated root canal posts are made solely of noble metals (e.g., 80 % Pt – 20 % Ir or 60 % Au – 20 % Pd – 20 % Pt), and others from titanium or a titanium alloy with 6 % Al and 4 % V. Stainless steel is not well suited for root canal posts, even if the posts are gold plated, because of its low corrosion resistance. Prefabricated posts come in different shapes and dimensions for different root sizes and purposes.

Precision Attachments. An important application of noble-metal alloys is in prefabricated precision attachments. Various anchors, hinges, bar joints, etc., are available, which are based largely on the male – female principle. They are used to couple different parts of a prosthesis (e.g., a removable partial to a fixed partial denture) and to achieve fastening and accurate location of the prosthesis. The advantage of these attachments is that the prosthesis or parts of it can be removed for inspection and repair, for cleaning, and for care of the adjacent oral tissue. Depending on the construction, indication, and intended joining technique (brazing, casting onto), precision attachments are made of high-melting, nonoxidizing alloys (e.g., Pt with 20 % Ir or Au with 15 – 25 % Pt and 15 – 25 % Pd) or of high-strength alloys based on the Au – Ag – PGM system or the Ag – Pd – Cu system.

Platinum Foils. A particular application of platinum foils (about 25 μm thick) is in the fabrication of full ceramic crowns (jacket crowns), in which a foil cap must conform to the die onto which a particular alumina porcelain is fired. After the firing operation, the platinum foil is removed, leaving a gap for cementation.

An alternative to this full ceramic crown is the platinum-foil-reinforced ceramic crown, in which the cap made from the foil is conditioned in such a way that the dental ceramics commonly used for veneering cast metal substrates can be fused to it, and the composite crown then cemented. Successful conditioning techniques are tin plating and oxidizing, fusing of gold bonding agents, or covering with a gold brazing alloy [1, 3, 4].

Tools, Sheets, Bands, and Wires. Stainless steel is the material from which not only instruments and tools for dentistry are fabricated, but sheets, bands, wires, etc., for intraoral application are made as well. Usually the 18 – 8 variety of austenitic steel is employed, whose corrosion resistance depends on proper processing, e.g., heat treatment or cold working. Occasionally, Ni – Cr and Co – Cr alloys are also used.

Orthodontic Materials. Arch bars, springs, and bands in orthodontic appliances are generally made of stainless steel and are constructed and joined by spot welding or, occasionally, by brazing with silver solder. Both these joining techniques can reduce corrosion resistance, but this is acceptable because such appliances are used temporarily. Nickel – titanium alloys have also become popular for use in orthodontic appliances. Stainless steel is also employed for prefabricated screws and brackets in orthodontic appliances; for matrix bands to support the filling material packed into the tooth cavity; and for pins to improve the retention of large amalgam or resin restorations.

3. Dental Ceramic Materials [21 – 23]

3.1. Ceramic Teeth

As early as 1774, Duchâteaux and Chémant reported the use of ceramic powders for fabrication of teeth. Fonzi, in 1808, was the first to fire platinum posts into teeth as anchoring elements.

Ceramic teeth were manufactured in 1838 (Ash, England) and 1844 (S. S. White, United States). Since 1950, demand for ceramic teeth has diminished continuously. Today, artificial teeth fabricated from resin materials are preferred due to their lower price and easier processibility.

3.1.1. Raw Materials

The formula for table china was the starting point for the development of ceramic powders for teeth; as a rule, this porcelain is composed of 50 % kaolin, 25 % feldspar, and 25 % quartz. Teeth made from this material, while functionally acceptable, were faulty aesthetically because of their excessively white opaqueness. The high content of kaolin is responsible for this white opacity because of the highly refractive, highly dispersed mullite that forms from kaolin during firing. For this reason, the proportion of kaolin in the formula was greatly decreased or eliminated. However, the mechanical properties of dental porcelain suffered as a result.

The formulas for today's dental porcelain powders usually include more than 90 % of a mixture of feldspar and quartz, the quartz component being 15 – 25 % of the mix. For this reason, the term "porcelain tooth" has been replaced in the newer literature by "ceramic tooth."

Feldspar. Feldspar is the most important raw material, in ceramic powders. High demands are made on its quality: it should be largely free of foreign phases and low in iron content because of the danger of discoloration. Norwegian and Swedish feldspars are well suited because they consist largely of orthoclase ($K_2O \cdot Al_2O_3 \cdot 6\ SiO_2$), with the following typical composition (mass fractions in percent):

SiO_2	65.0
Al_2O_3	18.5
K_2O	12.5
Na_2O	2.5
CaO	0.2
Fe_2O_3	0.02

Quartz. The quartz used must have a similar purity. Quartz decreases the melting range of the feldspar – quartz mixture and provides sufficient rigidity to the ceramic mass during firing by increasing its viscosity. This assures that the formed contours of the tooth are not lost during firing. Furthermore, the quartz content affects several important properties of the ceramic material: flexural strength, thermal expansion, resistance to thermal shock, and opacity. These properties depend not only on the proportion of quartz but, significantly, on how much of the quartz passes into the glassy phase and how much remains in the crystalline phase.

Occasionally, minor amounts of opacity-inducing materials such as kaolin, mullite, or carborundum are added to the mixture. Addition of flux powders, such as soda or calcite, can reduce the melting temperature.

3.1.2. Fabrication

The raw materials are crushed first in a jaw crusher or chaser mill and then ground in ball mills before being mixed in accordance with the prescribed formula (maximum particle size 150 μm). To achieve better results, the mixtures are customarily fritted first. For this step, the raw materials are placed in fireclay containers and fired between 1200 and 1400 °C until the feldspar has melted completely and the quartz has largely dissolved in the mass. The glass blocks that result from this process are again crushed and ground to a fine powder (maximum particle size 100 μm).

The starting material for tooth fabrication thus prepared must now be given a *color.* A large number of differently colored ceramic powders are needed, because manufacturers offer approximately 20 different shades of teeth. Furthermore, every tooth is built up of several differently opaque and variously shaded layers. The natural appearance required cannot be attained in any other way. Shading is provided by the pigments ordinarily used in ceramics, e.g., red-brown spinels (Fe, Zn, Cr, Al oxides) and yellow vanadium-containing ZrO_2. Precise control of the color values and the transparency of the powders are prerequisite to achieve the desired tooth colors. The fluorescence of natural teeth is imitated by using special fluorescing pigments or by adding lanthanide oxides to the starting frit. The colored powders are converted to plastic masses by use of appropriate organic additives, e.g., starch paste or oils.

Shaping teeth requires much manual effort. Two-part metal molds are generally used. The

labial layers of the tooth are placed in one-half of the mold and the lingual layers in the other. Posterior teeth are formed from occlusal and basal halves. To permit retention of the completed teeth in the denture base material, precious-metal shells (largely palladium) are mounted on the back of the anterior teeth. After firing, gold-plated posts are soldered to these shells. For posterior teeth, retention is provided by dovetail-shaped undercuts in the base region.

The filled halves of the form are pressed together for joining. When they are heated to 150 – 200 °C, the organic components lose their plasticizing effect and serve as binders. The formed teeth are then placed on ceramic firing plates and heated to 800 °C to volatilize the organic components. The tooth is finally fired at 1200 – 1350 °C for 8 – 30 min, depending on the manufacturer. Today, the vacuum-firing technique, introduced in 1949 by Gatzka, is used primarily. This produces teeth essentially free of pores, which is beneficial in terms of strength and polishability of the teeth and — by increasing the transparency — particularly desirable in terms of aesthetic effects. In this procedure, the furnace is evacuated to approximately 1 kPa. When the tooth surfaces have become sintered, firing is continued at atmospheric pressure; firing is complete when the tooth surfaces are smooth while the tooth contours are still unchanged. After soldering of the retentions and the required quality checks, the teeth are collected in sets according to color and shape (Fig. 8).

3.1.3. Quality Requirements

Quality requirements are defined in ISO Standard 22112 (Dentistry – Artificial teeth for dental prostheses). Porosity, color matching with the shade guide, and dimensional stability are particularly stressed. Additional requirements are tissue compatibility of the material, and observance of laws and regulations relating to protection from radiation. As a result, uranium salts, formerly added to achieve fluorescence, are no longer used.

3.2. Dental Ceramic Fused to Metal Restorative Materials

In the past, partial dental restorations such as crowns and bridges were fabricated entirely of precious metal. Today, standard practice involves casting the framework in metal and veneering this with a ceramic layer. After insertion, such a prosthesis can hardly be distinguished from natural teeth.

The first attempts of this sort were made in 1728 by Fauchard, who attempted to enamel a gold denture base. However, only in 1962, was Weinstein, an American, able to develop frits that achieved sufficient adhesion between metal and ceramic [24]. The bonding material

produced is related to enamel. The metal provides sufficient tensile strength, while the ceramic, glaze-like veneer affords great abrasion resistance, good tissue compatibility, and an esthetic appearance.

In the past, mechanical retention of the ceramic layer on the rough metal surface was thought to be a prerequisite for good adhesion between the two components. Today, more significance is attributed to adhesion through chemical bonding between the materials. Bond formation generally is ascribed to the presence of easily oxidized components, such as tin and indium, in the alloy (see Chap. 2). Presumably, the metal oxide layer between the metal and the ceramic, enriched through a so-called oxide firing step, provides the chemical bridge between the components [25].

3.2.1. Thermal Expansion

The durability of the bond between the metal and the ceramic depends particularly on the thermal expansion of the components [26]. If the difference in this parameter is too great, the ceramic inevitably will split away from the metal during cooling. Under optimal condition, the ceramic shrinks a little less than the metal during cooling; i.e., the ceramic has a smaller coefficient of thermal expansion than the metal. It is then under slight compressive strain, which avoids tensile strain that is absorbed less well by the ceramic. Ordinarily, metals have a higher coefficient of thermal expansion than glasses; the values of metals used for casting partial dentures are in the range of $130 - 150 \times 10^{-7}\ K^{-1}$ between 25 and 500 °C. Glasses with sufficient chemical resistance, however, have a significantly lower coefficient of thermal expansion. The required high coefficient is attained through the precipitation of a finely divided, dendritic form of leucite ($K_2O \cdot Al_2O_3 \cdot 4\ SiO_2$) as a crystalline phase in the glass during firing [27]. Leucite is transformed from the tetragonal to the cubic form in the range from room temperature to 620 °C. This transformation is accompanied by a 5 % increase in volume and thus is associated with a high coefficient of thermal expansion. A concentration of 20 – 30 % of leucite suffices to provide an adequate coefficient of thermal expansion to the ceramic. In theory, any frit that will precipitate the required amount of leucite through appropriate temperature handling suffices [28]. In practice, however, several frits of different composition are used, which permit better control of the properties of the ceramic and a broadening of the melting range; this simplifies subsequent firing of the ceramic to the bridge framework.

3.2.2. Raw Materials

Orthoclase (potassium feldspar) is the most important raw material for a ceramic that is to be fused to metal. To make a frit that easily segregates leucite, the potassium content must be increased, e.g., by adding potassium carbonate, K_2CO_3. Some manufacturers prefer to replace natural feldspar with a mixture of other raw materials, e.g., quartz flour, alumina, and potassium carbonate. Furthermore, the addition of flux powders, such as alkalis, alkaline earths, or boric acid, is necessary to lower the fusion range. The ceramic must be able to be applied at a temperature significantly below the softening temperature of the metal. Firing temperatures between 900 and 980 °C are customary, but temperatures as low as 750 °C are becoming increasingly common. The attainable decrease in the firing temperature is limited by the increasing chemical solubility of the ceramic.

3.2.3. Fabrication

The raw materials are first sintered into frits. The composition of ceramic materials varies greatly among manufacturers. This is caused, in part, by the practice of mixing several different frits. The main constituents of most of the relevant ceramic materials are present in these following ranges (mass fractions in percent):

SiO_2	58 – 66
Al_2O_3	15 – 17
K_2O	10 – 14
Na_2O	5 – 8
Li_2O	0 – 1
CaO	0 – 2
B_2O_3	0 – 3

A ceramic of this sort is made into ready-to-use powders by adding opacifiers and pigments to the frit, so that the final veneer corresponds in color to the shade guides provided.

Every veneer requires three different powders: the opaque, dentin, and enamel powders. The opaque ceramic provides adhesion and simultaneously prevents the metal from showing. To meet this function, it contains up to 12 % of opacifiers such as TiO_2, SnO_2, CeO_2, ZrO_2, or $ZrSiO_4$. Dentin and enamel powders make a toothlike appearance possible through their coordinated shades and translucence.

Figure 9. Cross section of a ceramic-fused-to-metal crown a) Metal substructure (0.2 – 0.4 mm); b) Opaque layer (0.2 mm); c) Dentin layer (0.6 mm); d) Enamel

The dental technician mixes the ceramic powders to a creamy mass using water or a special modeling liquid. Each of the three ceramic layers is applied and fired separately. Appropriate distribution of grain size of the ceramic powders assures sufficient contour stability and condensability of the ceramic pastes. The grain size is in the range of 2 – 80 µm, with a maximum between 20 and 30 µm. Each firing lasts about 5 min. The vacuum-firing procedure, described for tooth firing, has been widely adopted. If the veneer must be ground later for adjustment, glazing and refiring provide the necessary shiny appearance. Unpigmented, finely ground glass frits are used as glazes. They contain sufficient flux and can be fired at lower temperatures than those required for veneering. Strongly pigmented glazes are used to provide specific colors. For example, tooth necks can be accentuated with color, and superficial anomalies, such as enamel tears and white spots, can be copied. Figure 9 shows a cross section of a crown.

3.2.4. Quality Requirements

The requirements and testing procedures are defined in the standard ISO 9693. Important properties that must be checked constantly by the manufacturer include thermal expansion, adhesion to the metal, bending strength, firing shrinkage, chemical durability, and transparency and color of the fired ceramic materials.

3.2.5. Ceramic Fused to Titanium

Since about 1985, titanium has been used to a small but increasing extent as a framework material. Titanium has a lower thermal expansion (92×10^{-7} K $^{-1}$) than the traditional "ceramic alloys". Therefore, the ceramic does not require leucite to enhance its thermal expansion. The firing temperature of the ceramic must be below 850 °C, due to the high reactivity of titanium. The veneer ceramic consists predominantly of a leucite-free glass with an increased content of alkali metal oxide and boric acid.

3.3. Dental Ceramics for Fixed Restorations

3.3.1. Jacket Crowns

Long before the combination of metal and ceramic was accepted, damaged teeth were repaired exclusively with ceramic materials. The first success was achieved by H. Land, who introduced his jacket crowns in 1895 in the United States. In Europe they became popular only after 1918.

The following technique is used to fabricate a jacket crown: A model is made of a die of the prepared tooth. The model is covered with platinum foil; the foil serves as a base for the layers of ceramic to be placed on it. The foil is removed after the crown has been completed. As with ceramic-fused-to-metal restorations, several layers of ceramic, each with a specific transparency and shade, are fired. The core material

is covered with a dentin layer and then with an enamel layer.

The demands made on the ceramic's physical properties are different from those required of ceramic powders for application to metal. Because no metal base is present, the thermal expansion of the ceramic does not have to be increased, and the firing temperature does not have to be reduced below 1000 °C. Nor need the core material be extremely opaque. However, the absence of a support for the crown, otherwise provided by the metal framework, must be compensated by increased strength, at least of the core material. The flexural strength of this material should be at least 100 MPa, whereas 50 MPa is sufficient for the opaque material in the metal – ceramic technique.

Jacket crowns were fabricated in the past from ceramic powders quite similar to those used for teeth. This required that they had to be fired at temperatures no lower than 1250 °C. Today, ceramics are available which, through the addition of boric acid and other fluxes, can be fired at temperatures below 1100 °C. The necessary increase in bending strength of the core material is achieved by adding as much as 50 % alumina, usually in the form of carborundum [29]. Prerequisites to the increased flexural strength elicited by the carborundum are good binding with the surrounding glass matrix and a controlled difference in thermal expansion between the carborundum and the glass phase.

Because of the better mechanical properties of metal – ceramic crowns and because of their more readily attainable exactness of fit, they have largely replaced jacket crowns. But for patients with allergic reactions to precious metals, jacket crowns still find some use. Additionally, the lack of the opaque metal layer allows for a more natural appearance of the restoration.

3.3.2. Newer Developments

While the importance of traditional jacket crowns approaches zero, extensive efforts have been made to replace the metal frame by newly developed high-strength ceramic. Suitable ceramic materials, superior to the jacket crown material regarding their strength are readily available. Glass ceramics, for example, have flexural strengths up to 300 MPa, and oxide ceramics such as Al_2O_3 and ZrO_2 even up to 1000 MPa. While some glass ceramics have a tooth-like appearance, oxide ceramics can serve only as core materials because of their opacity and have to be veneered with more transparent ceramics. There are no generally accepted requirements for the strength of ceramics for dental restorations. The standard ISO 6872 requires a minimum flexural strength of 100 MPa for ceramic materials used for the fabrication of the supporting structure of crowns, veneers, inlays, and onlays. However, ceramics for crowning posterior teeth are only acceptable if they considerably exceed this minimum, and materials for bridges are expected to have flexural strengths above 300 MPa. Besides the dimensions of the restoration and the expected masticatory pressure, the durability also depends on the manner in which it is fixed to the prepared tooth. The main problem lies in manufacturing dental restorations from these ceramic materials at an acceptable price. The fact that each restoration has its individual dimensions which must be observed exactly exacerbates the problem.

There are several methods for shaping the ceramic material.

Sintering of ceramic powder has the problem that shrinkage during the sintering process means that the shape before and after firing differ considerably. In the case of metal – ceramic and jacket crowns, the inner surface of the restoration, which has to fit exactly to the prepared tooth, is determined by the metal frame or the platinum foil. During the firing process, the ceramic powder shrinks towards the metallic base. The form, which the dental technicians build up with the ceramic powder slip, must be oversized to compensate for the shrinkage.

Normally, glass ceramic is produced by casting of the glass melt into the desired form, followed by a tempering process, in which the glass partly crystallizes. Distribution, quantity, and size of the crystals are responsible for the quality and the properties of the material. But if the glass ceramic is sintered together from fine particles, it is hardly possible to achieve an optimal crystallization process, and the resulting material is inferior. Thus, for the production of glass ceramic restorations dense ingots are used, which are cast or pressed in a prepared form.

Dentsply introduced the first glass ceramic dental system Dicor in 1984. It was developed

jointly with Corning Glass Works. Its basis is a mica – glass ceramic [31]. The tooth crown was cast of a special glass at 1370 °C. A centrifugal casting procedure similar to that used for casting metal denture restorations was used. In the subsequent ceramic firing (14 h at 1070 °C), approximately 55 % of the glass crystallizes. The structure of the resulting translucent glass ceramic is characterized by platelike, interlaced crystals of a fluoride-containing mica with the formula $K_2Mg_5Si_8O_{20}F_4$. These crystals, approximately 1 µm in size, should lend strength to the material and retard crazing. A colored glaze is fired onto the structure to provide the desired shade [32]. The long–term success of this material was not sufficient; therefore it has been withdrawn from the market.

In 1990, Ivoclar introduced their Empress system [33]. This is also a glass ceramic system, but with some important differences compared to Dicor. The ingots are not cast but pressed into the form by a special hot-pressing device. For this reason, they have to be heated up only to the plastic state, and the reinforcing crystals present in the ingots do not dissolve during the hot-pressing process. This has the advantage that the time-consuming subsequent ceramic firing is not necessary. The crystal phase in Empress is leucite, but in contrast to metal – ceramics the crystallization process is optimized to give a flexural strength of about 150 MPa. Similar to Dicor, a colored glaze gives the desired shade. Similar systems from other manufactures are nowadays common.

Another way to overcome the problems associated with the sintering shrinkage is represented by In-Ceram, a product marketed by Vita Zahnfabrik since 1989 [34]. The model of the prepared tooth is duplicated with a special gypsum. An alumina powder slip is applied to this die and fired. Firing has to be timed in such a way that the alumina does not shrink and a porous, partially sintered preform is created. This preform is infiltrated with a glass melt in a second firing step. The resulting dense core has a flexural strength of more than 400 MPa. Therefore, this material is useful not only for inlays and crowns, but also for bridges. A toothlike appearance can be achieved by veneering the core with a more transparent ceramic.

In 1988, the first CAD/CAM system for manufacturing dental restorations was offered by Siemens. This CEREC-System was developed by Mörmann and Brandestini. It was suitable for the production of inlays only, but today, systems are available for the production of crowns and even bridges [35]. All these systems use industrially produced dense ceramic blocks as starting materials, they are therefore not confronted with the problem of shrinkage. The process can be divided into three steps:

1) Three-dimensional scanning of the surface of the prepared cavity or tooth stump by an optical or mechanical device and transmission of the data to a computer. Scanning can be performed either intra-orally or extra-orally after manufacture of a model from an impression. Instead of the cavity or the stump, a preformed model of the desired restoration can be used for the scanning process.
2) Design of the restoration using the three-dimensional computer model derived from the scanning device. The operator can either complete or change the restoration on the screen. The outer form with the occlusal surface can be designed with the assistance of different tooth forms stored in the computer's database.
3) Fabrication of the restoration from the ceramic block by a computer-controlled precision milling machine.

Many types of ceramic are applicable for this purpose, but ceramics with a glass-matrix are preferred because of their toothlike appearance and ease of grinding. The strength of these ceramics is sufficient for inlays and crowns, but for bridges oxide-ceramics have to be chosen. Most CAD/CAM systems can also be used for the milling of metal preforms.

The CAD/CAM systems are expensive but advantageous in that they allow the production and insertion of restorations at the chairside during a single visit.

CAD/CAM systems are also used to produce frameworks for full ceramic bridges even for the posterior region. Yttrium–stabilized zirconium oxide ceramic is mainly used for this purpose. Beside the main constituent zirconium oxide the ceramic contains 5 % yttrium oxide and a small amount of aluminum oxide. The main impurity is hafnium oxide, which is contained in an amount of approximately 2 %. The addition of yttrium stabilizes the tetragonal high–temper-

ature phase of zirconium oxide down to room temperature. Under the stress of a propagating crack the stable monoclinic phase is produced, associated with expansion. The pressure from this expansion stops further growth of the crack. This gives this type of material its high strength and durability.

Originally, frameworks of zirconium oxide ceramic were made from dense sintered material. Because of the rigidity of the material the milling process took a long time. Nowadays, mainly presintered material is used. It has a chalklike consistency and can be easily milled. To get a fitting restoration the computer calculates an oversized framework to be milled by taking into account the firing shrinkage. After dense sintering of the material the framework is veneered with a special veneering ceramic which is adjusted to the low expansion coefficient of zirconium oxide.

4. Cements

In dentistry the term "cement" is often used with two different meanings. Dentists use "cement" for all luting materials for the fixation of crowns, bridges, inlays, or onlay, even if the material is resin-based. Chemically speaking, the term "cement" describes dental materials that contain reactive fillers as one component of the setting system. Only these materials are treated in this chapter.

These cements can be classified according to their type of setting reaction:

– Neutralization reaction
– Complex formation reaction

4.1. Cements Setting by Neutralization Reaction

The development of amalgam, gold alloys, and dental porcelain in the 1800s led to the search for luting and more esthetic restorative materials. Cements composed of calcium oxide and phosphoric acid, magnesium oxide and solutions of magnesium chloride (magnesium oxychloride cement), or zinc oxide and zinc chloride solutions were developed. The first dental cement with satisfactory properties and relatively low pulp irritation was zinc phosphate cement. The most important properties of cements setting by neutralization reaction are listed in Table 6.

4.1.1. Zinc Phosphate Cements

Zinc phosphate cement (phosphate cement) was introduced in 1879 [93]. The powder contains zinc oxide and small amounts of magnesium oxide. The liquid is an aqueous solution of orthophosphoric acid (ca. 50 – 60 %) and aluminum phosphate. Both components may contain minor amounts of additives to improve various characteristics. During setting, the oxides are neutralized by phosphoric acid. Set cements

consist of unchanged zinc oxide particles embedded in an amorphous matrix of zinc phosphate and zinc aluminophosphate [94]. Due to the relatively low strength and the opaque appearance, zinc phosphate cements are used exclusively as luting materials for restorations.

Trade Names: Fleck's cement (Mizzy); Harvard Cement (Richter & Hoffmann).

4.1.2. Silicate Cements

Replacing the zinc oxide of zinc phosphate cements by ion-leachable glasses gives the silicate cements, first developed in 1902 [95]. Glasses are melted from silica, alumina, sodium fluoride, cryolite, and calcium sources such as calcium fluoride, calcium oxide, calcium carbonate, or calcium phosphate [94]. The liquid is similar to that used with zinc phosphate cements. In the setting reaction, the glass is attacked by acid, and metal ions are released and precipitated as phosphates. Unconsumed glass particles surrounded by silica gel are embedded in the phosphate matrix. Due to the fluoride content of the glass, silicate cements release fluoride. Strength and esthetics are better than those of zinc phosphate cements, but solubility is higher [94]. Old silicate cements led to some extent to pulp necrosis, an effect that was explained by the relatively high content of arsenic impurities in their glasses. But even cements with practically arsenic free glasses led to pulp sensitivity [96]. Possibly the slow increase in pH leading to a prolonged contact of the pulp with an acidic environment can explain these findings [94, 96]. The major use of silicate cements is in anterior restorations.

Trade Name: Silicap (Vivadent).

4.1.3. Silicophosphate Cements

Silicophosphate cements (stone cements) are a combination of zinc phosphate and silicate cements. The powder contains both zinc oxide and ion-leachable glass. Their properties are in between those of zinc phosphate and silicate cements [94]. They are used as filling materials, like silicate cements.

Trade Name: Drala Steinzement (Detax).

4.1.4. Zinc Polycarboxylate Cements

Zinc polycarboxylate cements were developed by D. C. Smith in 1964 and became commercially available in 1968 [93]. The phosphoric acid of phosphate cements was replaced by an aqueous solution of polyacrylic acid (20 – 60 %). Different additives to the powder (e.g., fluorides) are used to improve cement properties. Some products contain dried polyacrylic acid in the powder and are mixed only with water. The major new feature of these cements was their chemical adhesion to tooth tissue [93]. This property can be explained by the fact that the carboxylic groups of the polyacid react not only with the zinc ions released from the powder (setting reaction), but also with calcium ions of the tooth structure [94]. Zinc polycarboxylate cements have relatively low mechanical strength but are well tolerated by the pulp. For that reason they are used mainly as luting materials for metallic restorations and base materials.

Trade Names: Durelon (ESPE); Poly F Plus (Dentsply).

4.1.5. Glass Ionomers

History. A. D. Wilson investigated the use of ion-leachable glasses with polyacrylic acid. By increasing the basicity of the glasses, systems with acceptable reactivity were obtained in 1969 [97]. That class of materials was named glass ionomer (glass + ionic polymer) or glass polyalkenoate. The first glass ionomer ASPA I (**a**luminum **s**ilicate **p**oly**a**crylate) was used clinically in 1970 by J. W. McLean. Due to a short working time and a very slow setting, the workability was restricted [98].

Composition. All glass ionomers contain three essential components: an ion-leachable glass, a polycarboxylic acid, and water.

The first glasses were calcium aluminum fluorosilicate glasses (with small amounts of sodium and phosphorus), melted from the same raw materials as the glasses for silicate cements. A typical composition (G 200) is: SiO_2 30.1 %, Al_2O_3 19.9 %, AlF_3 2.6 %, CaF_2 34.5 %, NaF 3.7 %, $AlPO_4$ 10.0 % [2]. After introduction of the sandwich technique (1985), in which dentin is replaced by glass ionomer, and enamel by composite resins, the need for radio-opaque

glass ionomers became evident [98]. Modern glasses for glass ionomers contain heavy elements such as strontium, barium, or lanthanum. For the reactivity of glasses the content of aluminum and the formation of a glass matrix containing Si–O–Al bonds is important [99].

For extended use in dentistry an adjusted working and setting time is needed. Since these requirements are only partially realizable with the glass structure, the setting characteristic has to be adjusted by different techniques. Temperature treatment of the glass powders prolongs the working time [98], as does the reduction of reactive ions on the particle surface by a pretreatment with dilute acids [100]. Addition of tartaric acid as chelating agent prolongs the working time and accelerates the setting reaction [101]. Most modern glass ionomers contain tartaric acid as a setting modifier.

In the first glass ionomers, an aqueous solution of polyacrylic acid was used. Many commercially available products still contain such solutions, even though they tend to form gels at lower temperatures. Copolymers of acrylic and itaconic acid [98] or of acrylic and maleic acid [102] are used to overcome this problem and to increase reactivity. In some products the high ratio of maleic acid in the copolymer leads to a higher degree of cross-linking in the material, resulting in high mechanical strength. The use of polyvinylphosphonic acid [103] or copolymers of acrylic and vinylphosphonic acid [104] has also been reported. The polycarboxylic acids used in glass ionomer formulations have a molecular mass in the range of 10 000 – 100 000 and are used in concentrations of about 20 – 60 % (depending on the different products). Depending on the indication the powder : liquid ratio can vary in a wide range of about 1.5 : 1 to 4 : 1. All glass ionomers contain water, which is the reaction medium and the only liquid component for paste formation.

Setting Reaction. After the attack of the polyacid on the glass, cross-linking of polycarboxylate with metal ions released by the glass takes place. A calcium aluminum polycarboxylate matrix is formed, in which glass particles covered by silica gel and water molecules are embedded. As a result of ion hydration, the content of evaporable water decreases with time [105], while the cross-linking reaction still slowly continues. Both effects lead to an increase in mechanical strength and Young's modulus [106] and reduced wear [107] in the course of time.

Further Developments. In a search for improved wear resistance the cermet (**cer**amic **met**al) ionomers were developed in 1985 [108]. In these materials silver is sintered with the glass particles. In other products silver is added as a powder component.

By the use of dried polyacid in the powder setting time was prolonged. An improvement in handling characteristics was obtained by the introduction of capsules containing predosed components which are mixed mechanically.

Recently, highly viscous glass ionomers were developed. These materials have high strength, high wear resistance, and low solubility [109 – 113].

Properties. Glass ionomers adhere chemically to the tooth structure by the same mechanisms as zinc polycarboxylate cements. Due to the possibility of reformation of broken bonds during the remodeling of dentin, the bond has a dynamic character. In a humid environment neither shrinkage nor swelling is observed. Fluoride release [114 – 116] and recharge (e.g., from toothpastes) [117] explain why secondary caries are only rarely observed near glass ionomer fillings. Fluoride and calcium release promote dentin remineralization [118]. The very good biocompatibility of glass ionomers, demonstrated in many tests [119], led to their use as bone cements and bone replacement materials in orthopedic and ear – nose – throat surgery with good results [120 – 123].

Uses. Beside the major use as filling, luting, and base or core buildup materials [98], further indications are endodontic filling [124], fissure sealant [125], orthodontic luting material [126], filling material for open furcations [127], and retrograde root-filling material [128].

Trade Names: Ketac-Fil Plus (ESPE), Ketac-Molar (ESPE), Fuji II (GC), Fuji IX (GC) (filling materials); Ketac-Cem (ESPE), Fuji I (GC) (luting materials); Ketac-Silver (ESPE), Miracle Mix (GC); HiDense (Shofu) (Cermets); Ketac-Bond (ESPE) (base material); Ketac-Endo (ESPE), Endion (Voco) (root-filling materials).

4.1.6. Resin-Modified Glass Ionomers

In an attempt to combine the advantages of glass ionomers with those of composites, monomers and initiators were added to glass ionomers. Thus, parallel to the glass ionomer reaction a polymerization reaction can be started by photochemical or redox initiation [129]. Methacrylated polycarboxylic acids are also used [130]. Often these materials are called light-curing glass ionomers; the general term resin-modified glass ionomer cements has been proposed for this class of materials [131]. An interpenetrating network of ion-cross-linked polycarboxylate and poly(meth)acrylates is formed. To obtain compatibility of water-based glass ionomers and resins, all materials contain hydroxyethylmethacrylate and other hydrophylic monomers [93]. Due to the hydrophilicity, a relatively high swelling is observed. For this reason resin-modified glass ionomer cements are not recommended for cementation of all-ceramic restorations (cracking of such restorations was observed) [132 – 134]. Resin-modified glass ionomers have higher strength and better esthetics than conventional glass ionomers but a relatively low wear resistance. Depending on the amount of resins in the structure, these materials can be self-adhesive. Due to the ease of handling they are largely used in pediatric dentistry.

Trade Names: Photac-Fil Quick (ESPE), Fuji II LC (GC), Vitremer (3M) (filling materials); Fuji Plus (GC), Vitremer Luting (3M) (luting materials)

4.1.7. Polyacid-Modified Composites

Conventional and resin-modified glass ionomers contain all three essential components of a glass ionomer, which react spontaneously when they come into contact. In search of light curing "one-component-glass ionomers", water-free systems were formulated. The glass ionomer reaction takes place only on water absorption in the oral environment [135, 136]. These materials are known as polyacid-modified composites [131] or compomers (**comp**osite ion**omers**). These materials are composite resins containing ion-leachable glass fillers, polymerizable acids, polycarboxylic acids, and hydrophilic monomers that are compatible with the acids and facilitate water absorption for the glass ionomer reaction [93]. An important property is the ease of handling. Strength and esthetics are better than those of resin-modified glass ionomers and comparable to those of composites. However, they have no self-adhesion and only low fluoride release compared to glass ionomers. They shrink comparably to composites and show the same tendency to swell as resin-modified glass ionomers [132 – 134]. Resin-modified glass ionomers and polyacid-modified composites are often referred to by the collective term "glass ionomer composite hybrids" (or simply hybrids). For both classes the most important indications are in fillings, the luting of metallic restorations, or as a liner or base [94].

Trade Names: Dyract (Dentsply), Compoglass (Vivadent), Hytac (ESPE) (filling materials); Dyract Cem (Dentsply) (luting material).

4.2. Cements Based on Complex Formation

These cements harden by the reaction of a metal oxide, hydroxide or salt with a chelating agent. Chelates form a matrix in which the inorganic particles are embedded. These materials generally have low mechanical strengths and therefore their use is limited to temporary fillings or lutings, pulp capping materials or root fillings.

4.2.1. Zinc Oxide – Eugenol Cements

Zinc oxide – eugenol cements (ZOE cements) contain zinc oxide and eugenol (the principal component of oil of cloves) as essential components. In two-paste systems, zinc oxide is suspended in a vegetable or mineral oil, and eugenol is thickened with resins. Small amounts of water or acetic acid are added to initiate and accelerate the reaction. The strength of these materials is low, and their solubility is high compared to other cements. Depending on the powder/liquid ratio or paste formulation, temporary restorations, luting cements, or root canal sealers can be prepared. Similar systems are used as impression materials [94]. In some formulations part of the eugenol is replaced by *o*-ethoxybenzoic acid. These EBA cements are stronger. They are used for the same indications as ZOE cements [94].

Due to the phenolic character of eugenol, the use of certain resin-based luting materials after temporary cementation with ZOE or EBA cements is problematic (inhibition of polymerization by phenols).

Trade Names: Temp Bond (Kerr), Scutabond NF (ESPE).

4.2.2. Calcium Hydroxide Cement

First attempts to use calcium hydroxide in dentistry are dated from the late 1700s. Calcium hydroxide has an antimicrobial effect and induces the formation of secondary dentin. The calcium hydroxide has been used in pulp capping since 1859 [137]. Cements contain salicylate chelating agents that react with calcium hydroxide (e.g., methyl salicylate or butanediol-disalicylate) [138, 139].

Trade Names: Dycal (Dentsply), Alkaliner (ESPE), Life (Kerr).

4.2.3. Other Chelating Cements

Various chelating agents are used in dentistry, especially together with zinc oxide. Root canal filling materials containing a 1,3-diketone and eugenol-free temporary cements containing liquid carboxylic acids are known.

Trade Names: Diaket (ESPE) (root filling material); Temp Bond NE (Kerr), Freegenol (GC), Procem (ESPE) (temporary cements).

4.3. Standards

The international standards for dental cements are:

- ISO 3107, Dentistry – Zinc oxide/eugenol and zinc oxide/non eugenol cements
- ISO 6876, Dental root canal sealing materials
- ISO 9917-1, Dentistry – Water based cements – Part 1 Powder/liquid acid base cements
- ISO 9917–2, Dentistry – Water based cements – Part 2 Light activated cements

5. Synthetic Resins

Synthetic resins are of great significance in dentistry. Polymers of the polymethacrylate group have been in use since around 1934, and they are still used today [36].

5.1. Denture Base Resins

The first organic base material for dentures was hard rubber. Pink India rubber was vulcanized in a water-filled autoclave at ca. 140 °C. This denture base material was used in combination with porcelain teeth. The dental prostheses produced in this way were functional, but not esthetically pleasing. The India rubber procedure is of only historical interest today.

The basic process of denture fabrication has remained unchanged. A stone (gypsum) model of the jaw is prepared from an impression of the patient's oral cavity. The original shape of the denture base is molded in wax on the stone model. The artificial teeth, either of porcelain but today mainly of resin, are mounted on this wax rim. The wax denture on the stone model is then invested with gypsum in the lower half of a denture flask. Subsequently, the other half of the flask, open on the upper side, is attached and the wax model is embedded completely. The gypsum on top of the upper half of the mold is planed by pressing with a lid. After the plaster has set, the two halves are separated and the wax is removed by melting. The artificial teeth remain fixed in the upper half of the flask. In this way, a precisely fitting cavity is obtained in which raw, unvulcanized rubber or the resin mixture to be polymerized is pressed and hardened.

Insulation of the stone plays a decisive role in this process, because the resin must be kept separate from the plaster. Initially, dental technicians used ductile tinfoil, which could be adapted with perfect precision to the teeth on the free plaster surface of the model. Tinfoil also seals the doughy mass to be polymerized from the steam that can evolve from hot plaster. More conveniently, a coating consisting of a ca. 3 % solution of sodium alginate in water can be applied to the plaster surface. It reacts with the plaster surface to give a water-insoluble calcium alginate film.

The decisive breakthrough in denture base resins was the development of poly(methyl methacrylate) by Röhm. Roth, a dental technician, mixed ground poly(methyl methacrylate) with the methyl methacrylate monomer; this gave a dough that could be used to make a functional and aesthetically satisfactory dental prosthesis, as described above [37]. The polymer – monomer mixture solved two problems of methyl methacrylate polymerization simultaneously: (1) the pure monomer shrinks by ca. 20 % during polymerization and (2) it simultaneously releases a large amount of heat (56.6 kJ/mol).

Poly(methyl methacrylate) [*9011-14-7*] has a dominant position in dental resins; it meets best the following requirements of a denture material:

- Absence of taste or odor, even after long periods of wear
- Good tissue compatibility
- Good mechanical properties
- Exact reproduction of details of the model
- Dimensional stability
- Low water sorption
- Color stability
- Good aesthetic appearance
- Simple manipulation (no need for expensive equipment)
- Good reparability
- Ease of cleaning

Methacrylates are available as powder and liquid. The polymer powder, today usually bead polymer, is mixed with the liquid monomer in a weight ratio of (2.5 – 3):1. After a certain swelling time, doughs are obtained which can easily be manipulated by pressing, pouring, or molding.

Mineral pigments are the principal coloring agents used; organic dyes are less important. To avoid formation of stress cracks and improve mechanical properties, the liquid monomer generally contains up to 10 % of a cross-linking agent. Ethylene glycol dimethacrylate [*97-90-5*] is preferred. Depending on the polymerization initiator used, four types of materials can be distinguished: heat-, cold-, light-, and microwave-cured polymers.

5.1.1. Heat-Cured Polymers

The procedure developed by Roth is called the "*Paladon technique*" in dental laboratory technology. In heat-cured polymers, 0.1 – 0.5 % dibenzoyl peroxide [*94-36-0*] is generally used as the free-radical initiator.

After the resin dough has been added to the insulated plaster form and pressed, the form is placed in a hot water bath. Dibenzoyl peroxide decomposes between 80 and 100 °C and initiates the radical chain reaction. If heating is too rapid, polymerization proceeds too vigorously and a porous product is formed due to boiling of the monomer (*bp* 100.2 °C at 101.3 kPa). Therefore, the initial heating process should be held at 70 – 75 °C for 30 min; then the water bath is allowed to boil for an additional 30 min.

The resin can be added to the hollow mold by injection or by packing the negative mold and applying pressure with a pneumatic press. In the packing and pressing procedure, excess resin is placed in the denture flask and the two molds are joined under pressure; excess material is squeezed out between the casts. The flask is then opened, and squeezed out excess material is cut off. The closed flask is then placed in the water bath. Better fit can be obtained by using the injection technique [38]; in this case, the resin is injected under high pressure into the closed flask. The flask is then placed in the water bath and held under pressure until polymerization is complete.

Trade names: Paladon 65 (Heraeus Kulzer, Germany); SR 3/60, SR Ivocap (Ivoclar, Liechtenstein); Lucitone (Dentsply, USA).

5.1.2. Cold-Cured Polymers

In addition to the heat-cured polymers described above, cold-cured polymers (also called autopolymers) have increased in significance [36]. In cold-cured polymers, the polymerization is initiated by a two-component redox system, one component of which is in the powder and the other in the liquid. Such systems are usually composed of tertiary amines, e.g., *N*,*N*-dimethyl-*p*-toluidine [*99-97-8*] (1 – 2 %), and peroxides, particularly dibenzoyl peroxide (0.5 – 2 %) which has been used worldwide since about 1940 [39]. The addition of UV stabilizers is customary to reduce discoloration.

When the components of the redox system are combined, numerous radicals form which activate polymerization. However, the formation of inactive byproducts leads to a yellow-brown discoloration of the resin. Initiator systems that do not produce discoloration were developed in 1956 [40]; they consist of a 5-substituted barbituric acid combined with dibenzoyl peroxide or heavy-metal salts. The color stability of cold-cured polymers having this type of initiator system is so high that the quality of the polymer reaches that of heat-cured materials.

Cold-cured polymers are manipulated like the heat-cured polymers, but the ratio of monomer to polymer is higher (10 : 4 to 10 : 7), and polymerization takes place in the closed flask at room temperature in 10 – 30 min. If no injection pressure is used, i.e., in the completion of cast dentures with resin (partial dentures) and in the fabrication of complete cast dentures, polymerization is carried out in a pressure chamber at 0.2 – 0.3 MPa and 45 – 55 °C to avoid porosity of the product.

Cold-cured polymers are preferred today for repairing fractured prostheses and for relining poorly fitting ones. The cold-cured resins are also used almost exclusively for the completion of cast partial dentures.

For complete dentures, cold-cured polymers are injected. While heat-cured polymers show certain strain after cooling, which arises from differences in expansion coefficients between plaster and resin, cold-cured resins polymerize practically free of strain. This results in a better fit of prostheses fabricated from cold-cured resins.

Trade names: Palapress, Paladur (Heraeus Kulzer, Germany); SR 3/60 Quick (Ivoclar, Liechtenstein), Degupress (Degussa-Hüls, Germany).

5.1.3. Light-Cured Polymers

The first denture resin that was polymerized by the action of light from a halogen source was introduced in 1984 (Triad, Dentsply). The resin material is supplied in a ready-to-use form which eliminates the need for mixing in the dental laboratory.

Instead of methyl methacrylate, diesters of methacrylic acid with high molecular mass diols similar to bis-GMA (see Section 5.6) or high molecular mass urethane dimethacrylates are used as monomer.

The handling technique has been adjusted because complete investment in plaster is no longer possible, since the light must have access to the resin from all sides. For this reason, for example, pontics are provided in prefabricated standard sizes. A more detailed description of light curing is given in Section 5.6.2 on resin-based filling materials.

Trade name: Triad VLC, Eclipse (Dentsply, USA).

5.1.4. Microwave-Cured Polymers

The reaction of microwave-cured polymers is almost the same as for heat-cured materials. The main difference is that the flask is not placed in a water bath and heated to boiling temperature. Instead, the water contained in the gypsum in the flask is boiled by microwave energy. Since metal flasks are impermeable to microwaves, flasks for microwave-cured polymers are made from fiber-reinforced polyester. The initiator system must be adjusted to the polymerization process. Therefore only materials specifically designed for microwave curing can be used for this polymerization procedure.

Trade name: Acron MC (GC, Japan).

5.1.5. Other Denture Resins

Soft resins are used as liners of dentures. In the past, plasticized acrylic or methacrylic acid esters or esters of higher alcohols were used; however, they are not sufficiently durable. If made of silicones, the liners have better durability but insufficient bonding to the denture base material.

Many attempts have been made to replace methyl methacrylate as the denture base material by other plastics [41, 42]. *Polyamides* and *polyurethanes,* practically indestructible resins in the fabrication of dental prostheses, have failed because of their insufficient rigidity and their excessive water sorption. At one time, *polycarbonates* (e.g., Thermpont, Andoran, and Copodan) appeared to be alternative resins because of their high impact strength. However, their dimensional stability did not meet clinical

requirements [41]. The high sensitivity of these materials to the steam evolved during injection into the mold, was responsible for alterations in shape and color. Furthermore, polycarbonates are sensitive to alkali which is present in many denture cleansers and leads to the formation of strain, tears, and denture fractures. The special injection techniques required and the associated expensive devices have also contributed to the elimination of polycarbonates from the denture base market.

Resins based on *poly*(*vinyl chloride*) [*9002-86-2*] appear to have a better chance for use as denture materials. Copolymers of vinyl chloride, vinyl acetate, and methyl methacrylates (e.g., Luxene and Virlene) are used because of their constancy of shape, low water sorption, and high fracture resistance. They can only be handled in licensed laboratories and require relatively complicated and expensive special apparatus; their market share has, therefore, remained minor.

5.2. Acrylic Teeth [43]

Most artificial teeth set up in a denture base resin are acrylic teeth, made from poly(methyl methacrylate) and methyl methacrylate. The early problems of poor shade composition, shade durability, crazing resistance, and particularly, abrasion resistance have been solved. Today, resin teeth can replicate natural teeth perfectly. The resin tooth is built up from cervical, dentin, and incisal resins, each of which is colored to correspond to the appropriate tooth shade.

The layers are pressed into metal molds, one after the other, and heat-polymerized under pressure. To give greater hardness to the outmost (incisal) layer for greater abrasion resistance, ca. 10 % of a cross-linking agent, preferably ethylene glycol dimethacrylate [*97-90-5*], is added. The cervical material is not or only weakly cross-linked, because it then absorbs the monomer of the denture base resin dough more readily, which provides for better bonding of the acrylic tooth to the denture base.

Despite its high abrasion resistance, poly(methyl methacrylate) is not entirely satisfactory for teeth in the posterior region. The mechanical properties and the wear resistance of the resin can be increased enormously when it is filled with 30 – 60 % of very small (mean grain size 0.04 μm) particles of hydrophobic (fumed) silica (e.g., Aerosil, Degussa).

Trade names: SR-Orthosit, SR-Vivodent PE (Ivoclar, Liechtenstein) Vitapan (Vita Zahnfabrik, Germany).

5.3. Crown and Bridge Veneer Resins [44]

Resins are also used to veneer the visible parts of metal crowns or bridges. Today, polymers of high molecular mass methacrylic acid diesters are used almost exclusively for this purpose and for jacket crowns. The abrasion resistance of the methacrylates can be increased by adding inorganic fillers such as very fine grained silica, and fine grained glass or quartz (particle size < 1 μm)

5.3.1. Heat-Cured Resins

Heat-cured resins provide better results than cold-cured polymers for crowns and bridges. They are available as combinations of powder and liquid or as ready-to-use pastes. The resin pastes are molded directly on the metal framework by the dental technician and are then polymerized in a pressure vessel at approximately 0.6 MPa and 110 °C. Steam, water, or glycerol is used as the heat-transfer medium.

Trade names: SR-Chromasit (Ivoclar, Liechtenstein); Biodent K+B Paste (Dentsply, Germany); Vita Zeta (Vita Zahnfabrik, Germany).

5.3.2. Light-Cured Resins

A breakthrough, particularly in processing, occurred when light-cured crown and bridge veneer resins were introduced [45]. These materials consist of ready-to-use single-paste resins, which eliminates the need for mixing. Polymerization is induced by irradiation with light (wavelength 300 – 500 nm). An aromatic ketone or camphoroquinone is employed as photoinitiator; tertiary amines are frequently used as reaction promoters. Light-initiated polymerization can provide resins that are fully equal in quality to heat-cured ones.

Trade names: Signum + (Heraeus-Kulzer, Germany); Sinfony (Espe, Germany); Cristobal + (Dentsply, USA).

5.4. Resin – Metal Bonding

The question of adhesion between metal and resin is of great significance for denture resins and for crown and bridge veneer resins. Unfortunately, without special bonding processes, gaps form between metal and resin in cast prostheses after short periods of use. Bacteria and food debris can settle in these gaps, leading to discoloration at the metal – resin interface. The same problem arises in crowns and bridges. Formerly, the resin could be held to the metal framework only with mechanical devices (metal beads or wires), which may be visible through the resin.

In 1984, the *Silicoater technique* was developed, which solved the problem of adhesion between metal and resin for all precious and nonprecious alloys. In this procedure, a silane is pyrolyzed in a flame and the products are deposited on the metal framework, where an SiO_xC layer of 0.1 µm thickness forms. On this surface, another silane, such as 3-methacryloxypropyltrimethoxysilane [*2530-85-0*], can simply be painted. If the methacrylate monomer is then applied, it reacts with the silane. The metal-to-resin bond achieved in this manner is stronger than the self-tear resistance of the resin. The bond remains stable in the oral milieu [47, 48].

Another process of silane coupling between metal and resin is the Rocatec technique. In this process, introduced in 1989, the surface energy of the metal is increased by two-step sandblasting with aluminum oxide. The first step uses pure aluminum oxide, and the second step with aluminum oxide coated with a special glass, part of which remains on the metal surface after impact. A silane is then applied to the treated surface.

Other systems apply hydrophobic fluorinated methacrylates to the surface (Sebond-MKV), use a molecule containing an acidic group (SR-Isosit-Spectra-Link) or use tin plating and oxidation of the tin layer on the surface (OVS). Another method is bonding with 4-methacryloxyethyl-trimellitone-hydrid (4-META).

Trade names: Silicoater (Heraeus-Kulzer, Germany). Rocatec (Espe, Germany); Sebond-MKV (Schütz Dental, Germany); SR-Isosit-Spectra-Link (Ivoclar, Liechtenstein)

5.5. Resins for Orthodontics

Orthodontic treatment is used to correct the position of teeth. For removable orthodontic devices, cold-cured polymers, such as those described in Section 5.1.2, are used. For fixed orthodontic appliances, resins very similar in chemical composition to those used in cold-cured restorative materials are employed as adhesives.

Trade names: Orthocryl (Dentaurum, Germany); Super C Ortho (Amco, USA).

5.6. Restorative Resins

In the past, only silicate restorations and expensive fired porcelain inlays were available to provide "invisible" tooth restoration. Silicate cement fillings have insufficient durability because their surfaces wash out and they do not esthetically satisfy.

Soon after their discovery, cold-cured poly(methyl methacrylate) resins (Section 5.1.2) were also used for restorative fillings. However, the presence of amine – peroxide catalysts in the resins leads to a bright yellow discoloration after service periods of only a few months. Similarly, the abrasion resistance of the restoration is not sufficient. In addition, the high concentration of unconverted monomer remaining in the resin can provoke pulp irritation. Therefore, these resins have been replaced by the new filler resins described in the following paragraphs.

Bowen transferred the structural principle of an epoxy resin to a methacrylate material and thus gave the latter the excellent material properties of filled epoxies [36]. The key chemical in this method is the so-called Bowen monomer (bis-GMA)

which is made from bisphenol A di(2,3-epoxypropyl) ether [*1675-54-3*] and acrylic acid [*79-10-7*]: Bowen also proposed using a mixture of 70 % ground quartz glass (average particle size approximately 15 µm) and 30 % of bis-GMA [36, 49] . Not only is the composite made in this way much more rigid and harder than polymers of methyl methacrylate, but it also shrinks less during polymerization because of

the greater molecular mass per double bond. Today monomer mixtures of bis-GMA and triethylene glycol dimethacrylate [*109-16-0*], as well as other dimethacrylates which act as diluents and certain urethane dimethacrylates, are used. In addition, the high content of inorganic fillers greatly decreases the thermal expansion coefficient and thus approaches that of the natural tooth.

Bis-GMA [*1565-94-2*]

The important problem of matrix-to-filler bonding is solved by treating the inorganic filler material with special silanes [50, 51], e.g.:

3-Methacryloxypropyltrimethoxysilane [*2530-85-0*]

The silanol groups of the hydrolyzed silane react with the hydroxyl groups of the silica filler, and its methacryl groups enable copolymerization with the matrix resins to occur, thus providing a chemical bond between matrix and filler.

The structure and particle size of the inorganic filler material have also been modified. The relatively coarse-grained fillers of the first composite generations (especially quartz with a particle size of 15 – 30 µm) did not permit glaze polishing of the external surface of the restoration. The use of fumed silica with a particle size of 0.01 – 0.04 µm led to restorative materials whose surfaces were homogeneous and amenable to glaze polishing. These "microfilled" composites contain about 50 vol % fillers.

In a more recent development, glass particles (< 1 µm; barium or strontium silicate glass) are mixed with the fumed silica. Such composites, called hybrids, are characterized by particularly good mechanical properties, homogeneous surfaces, and good polishability. These materials contain ca. 10 wt % fumed silica and ca. 70 % glass.

Composite restorative materials are no longer limited to the anterior region. Nowadays they have the required strength and abrasion resistance for use on occlusal surfaces.

5.6.1. Paste – Paste Systems

The composites whose chemical composition is described in the previous section have been available as two-paste systems: base paste and catalyst paste [36, 50, 51]. Nowadays there are only a few materials of this kind available on the market.

The tooth-colored base paste contains a tertiary amine (1 – 2 %), and the catalyst paste contains dibenzoyl peroxide (1 – 1.5 %). The tertiary amine usually is *N,N*-bis(2-hydroxyethyl)-*p*-toluidine [*3077-12-1*]; it does not have as great a tendency for discoloration as the *N,N*-dimethyl-*p*-toluidine used earlier. However, UV stabilizers must still be added. The catalyst pastes have a strictly limited shelf life of approximately one year and must be stored in a refrigerator.

Before placement, the base and catalyst pastes are mixed in a 1 : 1 ratio. Depending on the particular product, the working time ranges from 1 to 2 min and the setting time from 3 to 5 min. Disadvantages of the paste – paste system are the severely limited shelf life of the peroxide paste and the still-unsatisfactory color stability. Furthermore, air bubbles are generated in the pastes during mixing which severely affect the quality of the restoration.

5.6.2. Light-Cured Polymers

Light-cured polymers do not have the disadvantages of the paste – paste systems described in the previous section. The light-cured composites are almost identical in composition to those materials described in Section 5.6. However, they consist of only one component that contains a photoinitiator system.

The advantages of light-cured composites over the paste – paste systems are

Immediate readiness for use
Fewer air bubbles because mixing is not required
Prolonged working time
Better color stability
Much longer shelf lives (three years)
No need for cool storage
Much higher reaction rate

The first radiation-cured composites were polymerized with UV radiation (320 – 440 nm) in the presence of an aromatic ketone initiator such as 1,2-diphenyl-2,2-dimethoxyethanone [*24650-42-8*]. At an irradiation time of 20 s, a maximum depth of cure of only 1.5 mm was attainable. Nowadays, visible light (380 – 500 nm) is used with camphoroquinone [*10373-78-1*] as initiator and certain aliphatic and aromatic amines as polymerization promoters, and only common halogen lamps (150 – 250 W) or blue LED lights are required. In addition, the risk of UV radiation to the dentist's and patient's eyes disappeared. The most important advantage of polymerization with visible light, however, is the much greater cure depth attained. Depending on the composite and the light source, curing depths of 4 – 8 mm can be attained after 20 – 40 s irradiation time. Fiberoptics conduct the light to the site at which radiation is required.

Trade names: Charisma, Soltaire 2 (Heraeus-Kulzer, Germany); Artemis, Tetric Ceram (Vivadent, Liechtenstein); Prisma TPH, Surefil (Dentsply, USA); Beautifil (Shofu, Japan); Clearfil posterior (Kuraray, Japan); Prodigy (Kerr, USA); Filtek (3M Espe, USA).

5.6.3. Ormocer-Based Filling Materials

In this type of polymer-based filling material, the main component of the monomer matrix is an organically-modified-ceramic (ormocer). This is a cross-linked silicone oligomer bearing methacrylate groups. Dimethacrylates are used as diluents. Initiators and fillers are like in the light-cured polymers (Section 5.6.2). Advantages of this type of material are:

- Lower polymerization shrinkage because of the size of the oligomer molecule
- Lower dissolution rate of residual monomers because of the hydrophobic nature of the molecule, and a higher probability of each monomer molecule being incorporated in the polymer network because of the multifunctionality
- Higher abrasion resistance compared to materials with the same type and size of filler particles

Trade names: Definite (Dentsply De Trey, Germany); Admira (Voco, Germany).

5.6.4. Sealant Resins

Fissures of the posterior teeth are potential sites at which carious lesions can arise. However, when these fissures are sealed with thin layers of bis-GMA or related compounds, the occlusal surfaces can largely be protected from caries. The sealant resins, like restorative resins, are available as cold-cured and light-cured systems.

Trade names: Estiseal F (Heraeus-Kulzer, Germany); Delton (Dentsply, USA).

5.6.5. Resin – Tooth Bonding

Adhesion of the resin to the tooth is very important because otherwise restorations have short lifetimes, and marginal gaps are formed between the restorative resin and the tooth [49, 51, 52]. These gaps can be sites of secondary caries. In general, no bonding occurs between tooth and resin, and the dentist must provide mechanical anchorage to ensure retention. However, when mechanical retention is used, a relatively large amount of sound tooth tissue is lost.

The *acid-etch technique* has been used to provide bonding of *enamel* to composite resins. The dental enamel surface was first roughened with an approximately 35 % solution of phosphoric acid so that microretentions result. A thin layer of resin of the bis-GMA type was then applied to the etched surface; the monomer penetrates the pores etched into the enamel and is firmly anchored there. Finally, the restorative resin was applied, and a mechanical bond formed between dental enamel and resin.

Adhesion to dentin can not so easily be achieved. It took a while until it was realized that chemical bonding is not the way to solve the

problem. With modern materials a smear layer that is formed on the dentin surface during cavity preparation is dissolved in an acid. Part of the inorganic material of the dentin is dissolved, too. Collagen fibers extending into sound dentin remain on the surface. The dissolved material is washed away or remains in the adhesive. The adhesive penetrates the collagen and a part of the dentin tubuli to form a hybrid layer. The methacrylate groups of the monomers in the adhesive provide chemical bonding to the filling material. Since moisture is always present at the dentin, surface monomers in the adhesive have to be hydrophilic.

Trade names: Scotchbond (3M Espe, USA); Clearfil bond (Kuraray, Japan); Dentin Adhäsit (Ivoclar, Liechtenstein); Syntac (Vivadent, Liechtenstein) Prime & Bond NT (Dentsply, USA);

5.6.6. Toxicology

The toxicology of restorative resins is an important international issue, especially because of the relatively high pulp toxicity of methyl methacrylate. For this reason, new monomers with high molecular mass have been developed, e.g., bis-GMA (LD_{50} 14.15 mL/kg) which is not orally toxic and does not irritate skin or mucous membranes.

Studies on the biocompatibility of restorative resins have increased enormously in the past few years. A series of important components of restorative resins has been examined for tissue compatibility, and none of the substances examined caused irritation [46].

5.7. Standards

The following international standards on polymer based materials apply:

- ISO 1567: Dentistry — Denture Base Polymers
- ISO 4049: Dentistry — Polymer-based filling, restorative and luting materials
- ISO 6874: Dentistry — Polymer–Based Pit and Fissure Sealants
- ISO 6876: Dental Root Canal Sealing Materials
- ISO 7491: Dental Materials — Determination of Color Stability
- ISO 10139–1: Dentistry — Soft lining materials for removable dentures — Part 1: Materials for short-term use
- ISO 10139–2: Dentistry — Soft lining materials for removable dentures — Part 2: Materials for long-term use
- ISO 10477: Dentistry — Polymer-Based Crown and Bridge Materials
- ISO 22112 Dentistry — Artificial teeth for dental prostheses

6. Impression Materials [53 – 61]

According to their handling (chemoplastic or thermoplastic) and their properties after setting (elastic or hard, reversible or irreversible), impression materials can be grouped as follows:

Chemoplastic
- *Elastic, irreversible*
  - alginate
  - elastomers
- *Hard, irreversible*
  - impression gypsum
  - ZOE paste
  - polymer

Thermoplastic
- *Elastic, reversible*
  - Hydrocolloid
- *Hard, reversible*
  - impression compound
  - wax – resin
  - gutta-percha

The oldest known impression material is plaster of paris (Dwinelle 1840). Dental compound (Stent 1840) and gutta-percha (1850) were developed for use as impression materials in the mid-1800s. Hydrocolloids (agar) were introduced in 1927 (Poller), zinc oxide and eugenol pastes in 1935 (Kelly); alginates in 1940 (Wilding); polysulfides and condensation silicone resins in 1955; polyether resin in 1964 (Espe); and addition silicone resins in 1976.

The principal requirements for impression materials are:

- Biocompatibility for patient and user
- Physical and chemical properties in accordance with the purpose of impression taking

(precision of the dies, recording of the function): Flowability during impression taking, detail reproduction, mechanical strength, dimensional stability of the impression, compatibility with the die material
– Efficient workability to optimal quality (lot consistency, storability, ease of dosing and mixing), hygienic aspects (disinfectability), ergonomically favorable methodology, economy

The dentist needs a large choice of impression materials, because they fulfill the requirements to different degrees. For each task a certain impression material is best suited. The choice of an impression material is mainly governed by the required precision of the die (documentation, type of dental restoration), the object to be replicated (shape and condition), and the method of impression taking. When equally good results can be obtained with different impression materials, ergonomic and economic aspects are decisive.

6.1. Elastic Materials

An important advantage of elastic materials is that it is possible to remove them from the object from which the impression is taken without breakage or extreme deformation, even when they fill undercuts.

6.1.1. Alginates

Alginates (see also → Polysaccharides) are derived from alginic acid, a polyuronic acid composed of up to 750 units of D-manonuronic acid and L-guluronic acid 1,4-glycosidicly linked. It is contained in the marine algae in the amount of 40 % (dry substance). It is almost insoluble in water but has a high ability to swell by the absorption of water.

Dental alginates are powder mixtures with the following composition: sodium alginate (10 – 20 wt %), calcium sulfate (10 wt %), trisodium phosphate (1 – 4 wt %), diatomite (70 – 80 wt %), color and flavor (1 – 2 wt %). Mixing with water gives a plastic mass which sets by chemical reaction to give an elastic hydrogel. Monovalent soluble salts of alginic acid (Na, K, NH_4 alginate) are precipitated as sparingly soluble Ca salts. Since 1980 no lead compounds are contained in alginate, and low-dust and no-dust versions are available. The reaction is prolonged to a practical duration by a retarder (trisodium phosphate) which initially reacts with the Ca ions. Fast- and normal-setting preparations are available. The filler (diatomite) influences the plasticity of the mixture as well as the strength and elasticity of the impression. The plasticity of the mixture can be influenced by the powder/liquid ratio, and the working time by the water temperature. Dosing is performed manually, and mixing manually or in a mixer. The hydrogel ages (syneresis) and is sensitive to environmental conditions. Storage in air leads to a significant shrinkage of the impression. Disinfection is possible if well-proven recommendations are followed. The die must be manufactured as soon as possible, preferably 15 min after removal of the impression from the mouth and not later then 60 min after removal if stored in a humidor.

Plastic deformations result from pulling over strongly curved parts of the impression. Thin bridges of the impression material tear off. Detail reproduction requires pressure during impression taking and is not as good as with reversible hydrocolloids or elastomers.

Handling is simple and cheap. Alginates are used in many ways: to obtain dies for documentation, for therapy planning, removable dentures and removable orthodontic devices. They are not suited for fixed restorations (crowns and bridges).

A 3 % aqueous solution of alginate is used to produce insulating layer on gypsum dies in dental polymer technology.

6.1.2. Elastomers

Silicones. Impression silicones can be differentiated into condensation cross-linked silicones (C-silicones) and addition cross-linked silicones (A-silicones).

In the case of *C-silicones*, organic polysilanols and polydimethylsilanediols are condensed to give macromolecules by cross-linking agents (tri- and tetrafunctional alkoxysilanes) and accelerators (e.g., tin octanoate and dibutyltin dilaurate) with cleavage of volatile byproducts (alcohols). Fillers (10 – 80 wt %) are used to adjust the consistency: extra fine, fine,

medium, heavy, and putty. Dosing and mixing of the base paste and hardener (as liquid or paste) are performed manually. The addition of colorants makes homogeneous mixing easier and allows materials of different consistency to be distinguished when combinations of materials are used.

In the case of *A-Silicones*, polyvinylsiloxanes and siloxanes with terminal SiH groups are additively coupled by a platinum(0) divinyltetramethyldisiloxane complex (Karstedt catalyst). Reactive oligomers are formed as discrete intermediates by transfer of H atoms to give dimethylene bridges without formation of byproducts (hydrosilylation). The polymerization reaction can be disturbed by catalyst poisons (local anesthetics, astringents, traces of sulfur from vulcanized latex gloves, accelerators and cross-linking agents of C-silicones). The consistency can be adjusted from low viscosity to putty by fillers (40 – 70 wt %) and softening agents or paraffin oil (5 – 10 wt %). The products consists of a base paste and a catalyst paste, which are

- Dosed and mixed manually
- Pressed out of a double cartridge by a static mixer (homogeneous mixing)
- Dosed and homogeneously mixed by a machine with a dynamic mixer

Stability of the flowable silicones during application results from their thixotropy (reversible sol – gel transformation).

By addition of small amounts of nonionic tensides, which lower the interfacial tension with respect to water, the wettability of the hydrophobic A-silicones is enhanced. During impression taking, A-silicones with added tensides remain mainly hydrophobic, since the tenside micelles align only during contact with the moist impression object. However, contact to the hydrophilic gypsum during die production is enhanced, and this avoids voids (bubbles) on fine edges of the die. This can be achieved by the treatment of nonhydrophilic silicone with a wetting liquid (tenside in ca. 40 wt % isopropyl alcohol).

A comparison of C- and A-silicones is given in Table 7.

A-silicones can be used for all kinds of impressions in dentistry because of excellent detail reproduction, high elasticity, and superior dimensional stability. They are neutral in taste and odor. They are especially suitable where high precision is needed (fixed restorations). In cases where other, cheaper impression materials fulfil the requirements for precision, A-silicones are not used.

Table 7. Differences between condensation cross-linking silicones (C-silicones) and addition cross-linking silicones (A-silicones)

Property	C-silicones	A-silicones
Flowability/plasticity	depends on consistency	depends on consistency
Detail reproduction	shift of details on shrinkage	high
Plastic/elastic transition	slow	easier to recognize
Resistance to deformation	depends on consistency	depends on consistency
Residual plastic deformation	higher	very low, even under high compression
Change in volume	contraction, depending on consistency, thickness of layer, and storage time	very low contraction
Storage of the impression	limited by shrinkage	indefinite, several die casts possible
Die material	galvanic die production limited	usable for all types
Disinfection	dimensional changes possible	without problems
Costs	low	higher

For silicones different impression methods exist. The highest precision is achieved with a combination of a high-viscosity material (putty) with a low-viscosity material (double-mixing impression, corrective impression, sandwich impression). Pressure during application and a dry impression object are important requirements for a successful impression of the prepared tooth substances. For functional impressions (full dentures) slowly reacting materials are advantageous.

Further uses of A-silicones are:

- Evaluation of the positional jaw relation of the patient (materials with a high Shore hardness)
- Duplication of dies in dental technology with low viscosity materials
- Rebasing of dentures with a soft A-silicone prosthetic material
- Soft A-silicone material in maxillofacial prosthetics.

Polyethers. A poly(ethylene oxide)/poly(tetramethylene oxide) copolymer with terminal aziridino groups (content in the base paste ca. 60 wt %) are linked additively by an organic sulfonium fluoroborate as starter (content in the reactor paste ca. 30 wt %). The consistency of

the pastes is adjusted by fillers and softening agents (triglycerides). Mechanical mixing is the method of choice. Cooling of the pastes results in substantial increases in viscosity and makes mixing difficult. Before use pastes stored in the refrigerator have to be brought to room temperature. Detail reproduction, plastic/elastic transition, permanent deformation, and dimensional stability are the same as those of A-silicones. Resistance to deformation during removal of the impression from the teeth and from the die is higher. Polyethers are hydrophilic. They can be stored in air indefinitely. In aqueous media they exhibit a small time-dependant swelling. The time available for disinfection is limited. Short-term taste disturbance may occur with some patients. The main use is for fixed restorations. Mono-phase impressions and one-time two-phase impressions with individual impression trays are preferred. The die material is gypsum. Galvanic die fabrication by silver plating is possible; copper plating is not recommended. A special polyether material for evaluation of the positional jaw relation is available.

Polysulfides. Polysulfide oligomers with terminal and side-chain SH groups are three-dimensionally linked at the SH groups by lead dioxide or manganese dioxide. An elastomer is created by polycondensation. The base paste consists of 50 – 90 wt % polysulfide oligomer and, depending on the consistency, 10 – 50 wt % filler (TiO_2) and softening agents (neutral oils). The reaction paste normally consists of 77 wt % PbO_2, 3 wt % sulfur, and 20 wt % filler, and softening agents. Newer products contain organic peroxides instead of PbO_2. Common are one-time impressions with two different consistencies and individual impression trays made of resin material. Handling, indication and properties are, at their best, comparable to those of C-silicones. The materials are sticky, biocompatibility is limited (Pb content), and taste and odor are unpleasant. The market share of this impression material is very small nowadays.

Agar hydro gels consisting of 8 – 15 wt % agar (a heteropolysaccharide from brown algae) and 75 wt % water are converted by heat to a flowable hydro sol and set again by cooling. Viscosity, plasticity, and elasticity are reversibly dependent on the temperature. Addition of glycerol (7 wt %) and borax (0.2 wt %) enhance elasticity and strength; fillers (7 wt % kaolin) affect the consistency. Potassium sulfate (0.1 wt %) compensates for the negative influence of borax on the setting reaction of gypsum. Antiseptic additives (thymol) prevent microbial contamination.

Hydrocolloid materials are distributed in tubes (tray material) or in bars (syringe material). They have to be conditioned by stepwise heat treatment (water bath with three tanks): liquefaction of the gel to a sol in boiling water, tempering for storage (62 – 69 °C); cooling to impression-taking temperature (45 – 45 °C). Low-viscosity hydrocolloid is placed on the impression object from a syringe, and then high-viscosity material is applied on top with an impression tray. Special impression trays are necessary that provide mechanical retention for the impression material and are equipped with channels for water cooling.

Detail reproduction of the hydrophilic material is very good, even under low pressure. Permanent plastic deformation is higher than with elastomers, and tear resistance is much lower. The field of use is impressions for fixed restorations (inlays, crowns, bridges). Results equal to those of elastomers are reached with correct handling. Disinfection is possible only with short contact time. Hydrocolloid impressions can not be stored; immediate casting of a die (gypsum) is necessary.

6.2. Rigid Materials

6.2.1. Plaster of Paris

A powder of $CaSO_4$ β-hemihydrate (90 wt %), fillers (alumina, $CaCO_3$, diatomite; 7 wt %), accelerators (K_2SO_4, NaCl; 2 wt %), color, and flavor is mixed with water (1.5 to 2 parts of powder, 1 part of water) and hardens to an irreversible rigid impression within 3 – 5 min. Flowability and plasticity can be satisfactorily adjusted by means of the water content and depend on the working temperature. The reaction is exothermic. Plaster expands slightly (max. 0.15 % linear). Detail reproduction is very good as long as no small parts of the impression break off and get lost. In the case of undercuts, the hardened material must be broken and put together again. Plaster impressions can be stored indefinitely. The material for die casting is also

gypsum. Before pouring in the die gypsum, the impression must be disinfected, watered, and treated with a release agent. The separation of impression and die gypsum is difficult, and the surface of the die can be damaged during this procedure.

Plaster of Paris is used for functional and anatomic impression taking of the edentulous jaw and fixation impression of restorations. It is rarely used for impressions since the introduction of alginate and elastomers. The procedure is unpleasant for the patient. Another use is fixation during determination of the positional jaw relation.

6.2.2. Zinc Oxide – Eugenol Pastes

The reactive components ZnO and eugenol (80 – 96 wt %) are supplied as two pastes, which are adjusted in consistency by oils (olive oil, mineral oil) and fillers (talc, kaolin, rosin, vaseline). Zinc acetate and magnesium chloride are used as accelerators for the formation of zinc eugenolate. Addition of a few drops of water during mixing enhances setting. Irritation of tissue by eugenol is possible. Impressions are taken from the wet mucosa with individual impression trays (functional impression with thin layers of paste; unwanted high-detail reproduction to avoid micromechanical influences on the mucosa by the prosthesis since the details especially those of the oral mucosa change rapidly). During removal from undercuts, plastic deformation of the impression occurs. Impressions can be disinfected and stored for a long time. The die material is gypsum. After setting of the die gypsum, the paste can be softened by immersion in water (70 °C) and pulled off. Zinc oxide pastes are rarely used nowadays (compression impression of the mucosa).

6.2.3. Resins

Self-hardening methyl methacrylate/poly(methyl methacrylate) systems are no longer used today for biological and methodological reasons. Polymeric materials for temporary rebasing of dentures can be used as impression materials to give a working model for a new denture. These materials consist of a polymer bead powder of higher acrylates [poly(ethyl methacrylate)], which is swelled for a few minutes in a mixture of phthalate ester and alcohol to give first a flowable and then a stable gel, without a setting reaction taking place. The mass reacts on short term loading with rebound (elasticity), and on long term loading with flow (plasticity).

6.2.4. Thermoplastic Impression Materials

Thermoplastic impression materials were formerly composed of natural materials (copal, shellac, colophonium, mastics, sandarac resin, carnauba wax, raw rubber). Today mainly synthetic resins, waxes, and fatty acids (stearic, palmitic, and oil acids) are used. Added to this are fillers and colors. The masses are reversibly plastified in a water bath or by a flame. They can be disinfected. Gypsum is used as die material. Thermoplastic materials belong to the oldest impression materials. Today their market share is low.

Thermoplastic impression compounds consist of resin, fatty acid, and filler in a ratio of 2/1/3. The usual filler is magnesium silicate (talc). The necessary plasticity for impression taking is reached at 50 – 45 °C. Hardening takes place above 37 °C. At room temperature the materials remain rigid, even under pressure. Today these materials are used in dentistry only as accessories during impression taking (individualization of impression trays).

Wax/resin materials contain 70 – 80 wt % synthetic resins, 15 – 25 wt % hard paraffin, paraffin oil, and fillers. Some products contain metal powders to enhance heat capacity. At mouth temperature the materials are flowable under the pressure from the soft tissues of the mouth (functional impression), and rigid at room temperature and pressureless storage.

Gutta-percha is the *trans* isomer of natural rubber. Impression materials contain 60 wt % gutta-percha, resins (25 wt %), and fillers (15 wt %). Gutta-percha is occasionally used for special impression tasks for removable prostheses and in maxillofacial prosthetics.

7. Dental Waxes

Waxes are used in rather large quantities in various dental laboratory and clinical procedures.

Different types of waxes are required for various applications. The differences relate chiefly to softening behavior and hardness, and the characteristics desired are usually obtained by blending natural and synthetic waxes. Waxes are not chemically uniform materials. They are defined only by their similar properties.

Natural waxes are obtained either from animals, mostly insects, or from minerals. In the dental literature, the following natural components are often cited: paraffin, ceresin, carnauba wax, candelilla wax, and beeswax.

Synthetic waxes, waxlike materials, and additives are often added to the natural waxes. Among these, the most important synthetic waxes are polyethylene wax, polyoxyethylene glycol wax, and esters of long-chain aliphatic alcohols and organic acids.

Various additives, e.g., resins, rosin, dammar, myricyl palmitate, or stearates, are added to special-purpose waxes. Coloring agents, usually fat-soluble dyes, are dissolved in dental waxes to differentiate the various types and to approximate the natural color of the gingiva and the teeth.

Most of the waxes and waxlike substances can be melted together to form mixtures that do not separate when cooled. In this way, any special dental wax required for specific dental laboratory and clinical applications can be made.

Dental waxes are generally used after being heated to a softened or liquid state. Below the melting point, a solid – solid change occurs in the crystal lattice; a wax should be molded above this temperature to avoid internal stress which can result in distortions of the pattern. The *advantages* of waxes include easy workability, good polishability, broad softening range, low viscosity when melted, hydrophobic behavior, and clean burnout. Among the *disadvantages* of waxes are high thermal expansion, formation of internal stresses, solid – solid transition, and low hardness at room temperature.

Some dental waxes are used as material for patterns in the lost-wax technique. This technique, also called the indirect technique, involves fabrication of a wax pattern, embedding it in an investment, burnout of the wax, and casting a molten alloy in the hollow space. Inlays, crowns, bridges, and the metal framework of partial dentures are constructed in this manner. Other types of waxes are used for bite registration, construction of trial baseplates for complete dentures, and temporary connection of fragments of a broken denture before a repair procedure.

Many types of dental wax are marketed. Their names indicate the uses for which they are intended:

modeling wax
casting wax, burnout wax, inlay wax
carding wax, setup wax
bite registration wax
blockout wax
baseplate wax
correction wax
sticky wax, adhesive wax.

Because of their particular importance, dental inlay casting wax and baseplate wax are treated in more detail in the following paragraphs.

Dental Inlay Casting Wax. Inlay wax is used to produce cast inlays. It is available in two slightly different types: type I for direct modeling in the mouth and type II for indirect modeling on the die. Both wax qualities must (1) burn out without residue, (2) have minimum thermal contraction, (3) be carved without chipping and flaking, and (4) be intensely colored. Type I must not solidify at 37 °C but should flow easily at 43 °C, whereas type II must still not soften at 34 °C and should flow easily at 40 °C. Inlay waxes contain a larger fraction of hard waxes, such as carnauba wax, than the related baseplate waxes.

Dental Baseplate Wax (Modeling Wax). Baseplate wax is preferred in the production of dentures to shape the denture base that is later made from resin. The waxes are mixtures of paraffin and beeswax with minor additions of carnauba wax. The modeling waxes are classified into three types which differ slightly in their softening range and hardness. The following requirements must be fulfilled: easy removal with boiling detergent solution, low thermal contraction, easy trimming and carving, and glossy surface after gentle flaming.

8. Other Model and Die Materials

The most important model material is dental stone (model gypsum); this is treated in detail

in Chapter 9. In this chapter, only model materials other than gypsum are treated briefly; these materials, however, are much less important than gypsum.

Die Cements. The composition of die cements is similar to that of the silicophosphate and stone cements described in Chapter 4. As a result of their poor physical properties, these materials are rarely used today.

Only small amounts of powder and liquid (acid) can be mixed to form a thick, homogeneous, plastic mix. For this reason, only small models or single tooth dies can be fabricated. The advantages of die cements are their high rigidity and good scratch resistance. Their disadvantages are poor flow rate, contraction during setting and storage, and the fact that they can be used only with compound impression materials.

Resins. Various resins which cure at room temperature are used as binders for chemically inert fillers. Methyl methacrylates, polyesters, epoxies, and ethylenimine resins are available commercially. Very fine quartz powder and metal powders are used as fillers; their chief function is to reduce shrinkage during setting. The materials are available as powder and liquid or as two-paste systems.

The materials are rarely used because of their disadvantages. Resins are very rigid and provide good reproduction of details. However, they require a long setting time, some products are sticky after mixing is complete, they are not compatible with all impression materials, and they contract during setting.

Metallic Materials. The *amalgams* used as die materials are identical with the silver amalgams described in Chapter 2. They cannot be used with elastic impressions because they must be placed by plugging. Hardness and absence of shrinkage are good; detail reproduction is satisfactory. Their use is restricted to small models or dies.

Electrolytic plating of the impressions with copper or silver and, more rarely, with nickel produces very good models and dies. However, plaster, alginate, and hydrocolloid impression materials cannot be electroplated. The impression, made conductive by dusting with metal or graphite powder (dental compound), is suspended in an aqueous electrolyte as the cathode. The main components of the electrolyte are copper sulfate or silver cyanide, respectively. Pure copper or silver is used as the anode. Appropriate selection of the bath and the electrical current leads to development of a thin, but smooth and homogeneous, coating of the impression. Detail reproduction, precision, and rigidity of the models are very good. To prevent deformation during manipulation, dental stone is cast into the plated impression. The only disadvantage is the time required for the plating procedure (up to 10 h).

9. Dental Gypsum Products

Gypsum materials have a wide spectrum of use in dentistry. In addition to their use as model materials, they also serve as impression plasters (Section 6.1.1), as a component of alginate impression materials (Section 6.2.2), and as a component of investment materials (Chap. 10). History, raw materials, phases of the $CaSO_4$–H_2O system, natural and byproduct gypsum, and production of calcium sulfate hemihydrate are described elsewhere (→ Calcium Sulfate) [62]. Dental gypsum products are classified by international standards:

Type 1: Impression plaster
Type 2: Dental plaster
Type 3: Dental stone
Type 4: Dental stone, high strength

Use as Model Material. A dental impression is a negative reproduction of the teeth and the oral tissues. By pouring a suitable model material into this negative form, the dental technician obtains a positive cast of the form and relationship of the teeth and oral tissues. Dental stone and high-strength dental stone are ideally suited for high-precision mastercasts. Dental plasters are suitable for study, repair, and reference casts.

Requirements. The requirements for such a material depend on the purpose for which it is used: *type 2 dental plaster* should be easy to manipulate and show a smooth surface; *type 3 dental stone* and *type 4 dental stone, high strength* should be easy to manipulate, be compatible with common impression materials, have a very good fluidity in the plastic phase thus needing a short time for vibration, and have a short setting time (max. 30 min). On the other hand, the

Figure 10. Measurement of dimensional change of dental stone
A: In a closed extensometer at 23 °C
B: With side plates removed (23 °C, 50 % relative humidity) 2 h after start of mixing
C: Immersion in water bath for 5 min after 24 h
a) Dial gauge; b) Movable front plate; c) Removable side plates; d) Polytetrafluoroethylene (PTFE) sheet

setting time must be long enough to facilitate pouring of the impression [62 – 64].

In addition to the requirements mentioned above, the final model should show the finest details; have a smooth surface without pores; have sufficient strength, hardness, and wear resistance; and have a constant volume (small expansion is better than even minimal shrinkage) [63, 64].

The requirements for hardness, compressive strength, and the maximum linear setting expansion are different for all four types of gypsum. None of the model materials of type 2 – 4 can fulfill perfectly all the requirements mentioned. Dental stone high strength fulfills them best and is therefore the most common model material for casts used for the construction of inlays, crowns, bridges and removable partial or full dentures [63, 64].

Chemical Composition. Calcium sulfate hemihydrate occurs in two phases: α and β (for more details, see → Calcium Sulfate). The composition of dental gypsum products are as follows:

- Type 1 impression plaster (see Section 6.2.1).
- Type 2 dental plaster consists of β-$CaSO_4$ hemihydrate and modifiers.
- Type 3 dental stone consists of α-$CaSO_4$ hemihydrate crystals with a small specific surface and modifiers.
- Type 4 dental stone high strength consists of an α-$CaSO_4$ hemihydrate that has been dehydrated in an autoclave with special solutions [65]. This type also contains modifiers, added by the manufacturer to obtain the properties of the final product required by national and international specifications.

Typical ionic additives are potassium sulfate, potassium citrate and sodium potassium tartrate.

Water-soluble melanine resins are used as nonionic additives to increase the fluidity of the water – hemihydrate mixture. All these modifiers influence the setting expansion, the setting time, the hardness of the dental stone, and the morphology of the dihydrate crystals. Potassium-containing additives can produce crystals of syngenite (potassium calcium sulfate), which can appear as efflorescences on the surface of dental casts [66 – 68].

The *setting time* [69 – 72] can be shortened by (1) addition of inorganic acids and their salts, such as calcium sulfate dihydrate, 3 % sodium sulfate; 2.5 % sodium chloride, or 2 – 3 % potassium sulfate; (2) intensive and extended spatulation (excessive spatulation destroys the crystal structure and decreases strength); and (3) low water-to-powder ratio.

The setting time can be prolonged by (1) addition of organic acids and their salts as well as the presence of organic colloids such as dried blood or gelatin; (2) addition of salts of phosphoric and boric acids; (3) addition of more than 3 % of sodium chloride; (4) presence of nitrate or citrate; and (5) high water-to-powder ratio [62].

The setting reaction does not completely convert the calcium sulfate hemihydrate to dihydrate. Residual hemihydrate is present in the structure of fully set casts [66].

Physical Properties. The *strength* of hardened calcium sulfate dihydrate is directly proportional to its density; therefore, the strength depends on the ratio of water to hemihydrate powder and on the porosity of the hardened plaster or stone. Dental α-$CaSO_4$ hemihydrates (stones) need small amounts of water for mixing and fluidizing and therefore have a high density and great strength; however, they are brittle. The strength of calcium sulfate dihydrate also depends on the humidity of the atmosphere during storage.

The *hardness* of rehydrated type 3 dental stone and type 4 dental stone high strength increases with the time of storage. Chemically produced gypsum reaches its final hardness after 4 d, whereas natural gypsum needs 6 d. Due to sedimentation, the hardness of a cast is greater on the bottom than on the surface, where more pores are located [62, 73 – 75].

The hardness can also be influenced by contact with some impression materials. Contact with hydrocolloids, condensation-cured silicones, and polyethers lowers the hardness. This tendency can be reduced if the impression with the mixed hemihydrate is stored at 95 % R.H. for 30 min or during the entire setting period [62].

Volume Change. The absolute volume of a mixture of $CaSO_4$ hemihydrate and water first decreases when $CaSO_4$ dihydrate is formed. The contraction can only be measured for a short time after mixing [71, 76 – 79]. As soon as the rehydrated gypsum hardens, expansion starts. The thermal expansion during setting is reversible, but the setting expansion is almost irreversible. This setting expansion is influenced by (1) the water-to-powder ratio: the lower the water content, the greater is the expansion; (2) the presence of chemicals: for example, potassium sulfate lowers the expansion but also the strength; (3) the climate: storage of a model of type 4 dental stone high strength after the removal of the impression at 23 °C and 50 % relative humidity results in a contraction of about 0.05 % of its highest setting expansion within 7 d (Figs. 10 and 11); and (4) spatulation: high intensity and long time of spatulation of the water – hemihydrate mixture increase the expansion of type 3 and type 4 dental stone.

Figure 11. Dimensional change of dental stone model (at 23 °C and 50 % rel. humidity) as a function of storage conditions [62, 76]
A: Storage in a closed extensometer
B: Storage at 23 °C and 50 % relative humidity
C: Immersion in water bath for 5 min and subsequent storage as in B
For experimental conditions of A, B, C, see Figure 10.

The results of the setting expansion depend on the method and time of measurement (Figs. 10 and 11). The dental gypsum products are measured in an extensometer with a length of 100 mm [64]. The material of the surface of the extensometer in contact with the water – dihydrate mixture can influence the setting expansion [97].

Quality Standards. The Technical Committee 106 of the ISO has published ISO Standard 6873 (1998) Dental Gypsum Products. This standard also specifies the corresponding test methods.

Table 8 shows the ISO requirements for four different types of dental gypsum products. Table 9 compares the results obtained for various commercial products.

Storage and Packaging. Types 3 and 4 stones should be packed and stored in protective, moistureproof, and sealed containers. Each container must at least be marked clearly with the following information: name and/or trademark of the manufacturer, type, lot number, date of packaging, and date beyond which the material should not be used without retesting when stored under the recommended conditions: ca. 23 °C and not more than 50 % relative humidity.

Trade names: Type 2: Snow White Plaster No. 1 (Kerr); Alabaster (Dr. Böhme); Laboratory Plaster (Whip Mix).

Type 3: Castone, R & R Lab Stone (Dentsply); Coecal Buff, White (Coe Lab.); Octa-Mol (Heraeus-Kulzer); Modelit (Dr. Böhme); Microstone, Quickstone (Whip Mix).

Type 4: Duralit (DeguDent); Duroc (Dentsply); Begodur (Bego); Octa-Stone (Heraeus-Kulzer); Gilstone (Giulini); Silky-Rock (Whip Mix); Super-Cal Dental Stone (Coe Lab.); Tewestone (Kettenbach); Vel-Mix (Kerr).

10. Dental Investments

An investment is generally a powder mixture which can be mixed with a liquid to give a flowable paste that sets in a given time. The refractory material allows heating above 1100 °C. These properties make the material suitable as a mold material for alloy casting.

In dental technology a model is made from an impression that reproduces the teeth. The wax pattern (or resin, adapter cap) is shaped on this model. The pattern is removed from the model and provided with sprues on a base former and a casting ring. The mixed investment material is then poured into the casting ring. After hardening of the investment, the mold is heated to burn out the wax model. The casting mold is brought to the final temperature required by the particular alloy. After casting the object is divested and is ready to be worked on.

Classification. Investments can be classified according to the nature of the bonding material (gypsum- or phosphate-bonded) or the purpose for which they are produced (Co – Cr castings, precious metal castings, soldering of metallic parts, ceramic pressure technique).

Requirements. Investment casting materials should fulfill the following requirements:

- Expansion control: diluting the liquid component of phosphate-bonded investment materials with distilled water allows the expansion of an investment to be controlled in a way that the contraction of the particular casting alloy is compensated
- A suitable setting time
- Creamy consistency during investment
- Production of a smooth surface and reproduction of fine details
- No cracking during heating and on impingement of the molten alloy
- Compatibility with the alloys
- Keeping the high thermal expansion during the entire time of casting and reversible thermal expansion on cooling
- Easy removal from the cast object
- A possible additional requirement is suitability for the rapid-burnout method.

Chemical Composition. Casting investment materials consist of bonding and refractory materials. The refractory materials such as silica, usually quartz or cristobalite or a mixture thereof are responsible for the thermal expansion. α-Cristobalite changes reversibly into β-cristobalite, and α-quartz into β-quartz. These two crystal structure transformations result in the reversible thermal expansion of an investment. Standard investments need time for these

Table 8. Requirements and limits for types 1 – 4 dental gypsum products according to ISO Standard 6873. Working time and setting time are measured from the first contact of hemihydrate and water; the setting time must be within ± 20 % of the time given by the manufacturer.

Type	Testing consistency, mm	Pouring time, min	Setting time, min		Setting expansion, %	Compressive strength, N/mm^2	
		min.	min.	max.	max.	min.	max.
1	80 ± 4	1.25	2.5	5.0	0.15	4.0	8.0
2	75 ± 4	2.5	6.0	30.0	0.30	9.0	
3	30 ± 3	3.0	6.0	30.0	0.20	20.0	
4	30 ± 3	3.0	6.0	30.0	0.15	35.0

transformations to take place without formation of cracks; hence, holding times at 270 and 573 °C are needed during the heating process.

Gypsum-Bonded Investments. The bonding material is α-calcium sulfate hemihydrate $CaSO_4 \cdot 0.5\,H_2O$, which is converted to calcium sulfate dihydrate $CaSO_4 \cdot 2\,H_2O$ by mixing with water. The excess water is vaporized during initial heating to about 100 °C, and above this temperature water of crystallization is driven out of the investment. After reaching a temperature of 150 °C, gypsum-bonded investments either show a slight thermal contraction or remain unchanged up to 225 °C. At higher temperatures, the presence of silica dominates the thermal expansion. Gypsum-bonded investments should not be heated to temperatures exceeding 700 °C. Beyond that point, gypsum decomposes in the presence of silica to liberate sulfur dioxide, which causes porosity and corrosion of the casting.

$$2\,CaSO_4 \rightarrow 2\,CaO + 2\,SO_2 + O_2$$

Expansion control of gypsum bonded investments is achieved by varying the mixing ratio with water.

Phosphate-Bonded Investments. High-temperature investments require a bonding material other than gypsum. This bonding material consists of magnesium ammonium phosphate or a soluble acid phosphate such as ammonium dihydrogenphosphate and a metal oxide such as magnesia. These materials are mixed with an aqueous silica sol. The following simplified chemical reaction occurs during setting at room temperature and gives the investment the green strength before heating:

$$(NH_4)\,H_2PO_4 + MgO + 5\,H_2O \rightarrow MgNH_4PO_4 \cdot 6\,H_2O$$

The next reaction takes place during heating, water and ammonia are evolved above 200 and 300 °C, respectively.

$$2\,(MgNH_4PO_4 \cdot 6\,H_2O) \rightarrow Mg_2P_2O_7 + 13\,H_2O + 2\,NH_3$$

The silica-catalyzed decomposition into magnesium diphosphate increases the strength and hardness of the phosphate-bonded investment. By heating above 1000 °C with MgO surplus the following reaction takes place:

$$Mg_2P_2O_7 + MgO \rightarrow Mg_3(PO_4)_2$$

Physical Properties. The most important physical property of a dental investment material is expansion. The expansion is the sum of setting and thermal expansions and is responsible for the outstanding accuracy of dental restorations.

Setting Expansion. The setting of the phosphate-bonded investments is accompanied by the evolution of heat. At the end of the reaction process, the temperature reaches a maximum of 55 – 80 °C. This temperature increase affects the setting expansion. A standardized method for measurement of the setting expansion is presently under discussion. The setting expansion constitutes about 30 – 50 % of the thermal expansion and is caused by the reaction of the bonder. The bonder transformation separates the quartz and cristobalite grains and the result is an increase in volume. This process is intensified by mixing the powder with a special liquid and causes aqueous silica particles to crystallize to long needles.

The setting expansion of gypsum-bonded investments is based on the same principles as for gypsum products in Chapter 9.

Thermal Expansion. When dental alloys are cast, they contract on cooling. For this reason, thermal expansion is very important for dental investments and should compensate for the shrinkage of the casting alloys; however, the two materials have different thermal contraction curves. The thermal expansion of the investment materials depends on their composition and, in the case of phosphate-bonded investments, on the dilution of the liquid component and the particle size of the silica. The thermal expansion curves for quartz and cristobalite are very much different. Moreover, both silica modifications show a phase transition, each at a different temperature: quartz at 573 °C and cristobalite at 200 – 270 °C. All modifications of silica show a break in their expansion curves. Therefore, the thermal expansion curves for investment materials are very complicated.

Setting time of phosphate bonded investment materials is dependent on the reaction time of the two bonding materials and consequently on their mixing ratio and their grain size. Gypsum-bonded investment materials include small amounts of chemical additives which influence the setting time.

Hardness. All dental investments need enough hardness to resist the high temperatures and the casting impact.

Quality Standards. The classification and requirements for investment materials together with the corresponding test methods are described in the standards ISO 9694 (Dental Phosphate-Bonded Casting Investments, 1996) and ISO 7490 (Dental Gypsum-Bonded Casting Investments 2000).

Application. In general, the instructions of the manufacturer should be strictly followed for optimum results. Gypsum-bonded investment materials should not come into contact with phosphate-bonded investment materials. For gypsum- and phosphate-bonded investment materials, the use of separate mixing bowls and spatulas is necessary. Standard investment materials need preheating with holding times to withstand the quartz and cristobalite phase transitions without cracking. Rapid-burnout investment materials can be preheated in an oven at the final temperature. Exact ratios of the bonding and the silica materials and the use of special liquid components are the reasons for these robust properties. The advantages are that they do not require preheating in a controlled oven, have shorter heating times, and save energy.

1. Functions and Structure of the Skin

Functions. The skin is a three-compartment organ that serves several essential roles for the human body. As the major protective barrier between the body and the environment, the skin minimizes the potentially harmful effects of ultraviolet radiation, temperature extremes, microbial infection, and mechanical, chemical, or electrical trauma.

The skin is also an important sensory organ, containing nerve endings receptive to pressure, pain, and temperature. It protects against changes in body fluid status and provides a major means of thermoregulation through changes in the vascular system and evaporation of sweat.

Elimination of biochemical wastes and xenobiotics is accomplished in the skin by metabolic and excretory pathways, including sweating. Various synthetic activities may also occur, including sunlight-mediated production of vitamin D from precursors present in the epidermis.

Structure. The outer protective layer of the skin, the epidermis, is a thin, stratified squamous epithelium composed primarily of keratinocytes, melanocytes, and Langerhans cells. The epidermis (ca. 0.07 – 0.1 mm thick) lacks blood vessels. Keratinocytes, the predominant epidermal cell type, synthesize keratin, an insoluble fibrous protein, which is responsible for the protective qualities of the epidermis and is the structural component of hair and nails.

Keratinocytes originate in the innermost or basal layer of the epidermis and undergo a multistage differentiation process. This maturation process, termed keratinization, occurs as the cells migrate toward the surface and culminates in formation of a flattened, dehydrated, compact outer layer (0.01 mm thick) of nonviable horny cells. This layer, the stratum corneum, plays the critical role in the barrier functions of the skin and has significant water-retaining properties. It is composed primarily of keratin and lipids. Continuous shedding of surface cornified cells, i.e., desquamation, results in regeneration of stratum corneum approximately every 14 days. Complete epidermal turnover takes ca. 28 days.

Melanocytes originate from the neural crest and produce melanin, a pigment that largely determines normal skin color. Together with keratin, melanin protects the underlying basal layer against ultraviolet radiation damage. Located in the basal layer of the epidermis, melanocytes synthesize pigmented granules called melanosomes that are released from the dendrites of the melanocytes and transferred to adjacent keratinocytes through a phagocytic process. The number and size of melanosomes determine normal skin complexion and the degree of protection against UV-B radiation (280 – 320 nm) penetration. Sun-induced tanning is a delayed response that results from increased production of melanin.

Langerhans cells are dendritic cells involved in immune functions of the skin. These cells are responsible for uptake and transfer of antigens from the epidermal surface to T-cell lymphocytes, thereby initiating delayed hypersensitivity reactions.

The *dermis,* which forms the 2 – 3-mm-thick middle layer of the skin, consists of dense connective tissue with collagenous and elastic fibers dispersed in an amorphous ground substance composed primarily of glycosaminoglycans.

Collagen is a long, thin fibrous protein that accounts for the bulk of the dermis and lends strength and flexibility to the skin. Elastic fibers, consisting of protein fibrils and an amorphous protein, elastin, are primarily responsible for maintaining the skin's elasticity.

The dermis is rich in smaller blood vessels, lymphatic vessels, and nerves. The major cells of the dermis include fibroblasts, which are necessary for tissue repair, phagocytic histiocytes, and mast cells, which contain histamine and other chemical mediators of inflammation.

Underlying the dermis is the *subcutis,* a thick inner layer of protective connective tissue. Subcutaneous tissue contains large blood vessels and nerves, as well as numerous adipocytes, which manufacture and store fat. The subcutis also serves as a cushion to external impact and is an effective heat insulator.

Sebaceous glands, apocrine and eccrine sweat glands, and hair follicles may originate in the dermis or subcutaneous tissue and extend upward to the skin surface.

The structural and physiological properties of the skin account for its intrinsic impermeability and enable it to effectively perform its many protective functions. The same qualities, however, contribute to the difficulties associated with topical drug therapy. The factors that influence drug penetration through the skin, i.e., percutaneous absorption, are briefly discussed in Sections 2.2 and 2.3.

2. Topical Therapy

Topical application of drugs to the skin is often desirable in treating dermatological and, less commonly, systemic disorders.

Systemic administration, although advantageous in some skin diseases, is frequently limited by (1) failure to achieve therapeutic concentrations of many drugs, particularly in avascular regions of the skin and (2) unwanted pharmacologic effects outside the skin. Topical therapy allows for selective treatment of skin disease while the possibility of systemic adverse effects is minimized. Topical therapy generally does not result in appreciable levels of drug in the systemic circulation; however, some therapeutic agents, e.g., nitroglycerin [*55-63-0*] and scopolamine [*51-34-3*], have been successfully delivered transdermally.

2.1. Topical Dosage Forms

A wide variety of dosage forms exists for the topical delivery of medicinal compounds to the skin. Although systemic absorption can be either a deliberate or unintentional consequence of topical application, the action of topically applied drugs is most often limited to the site of application. Local therapeutic action is enhanced by formulations that promote prolonged contact with the target area while reducing the likelihood of absorption. Semisolid preparations, such as ointments, pastes, creams, and gels, fulfill these criteria to varying degrees. Unlike hydroalcoholic solutions, powders, and suspensions, which may be used to deliver drugs topically as well as by other routes of administration, semisolids are used exclusively for topical drug delivery.

Semisolid ointment bases are used primarily as vehicles to prepare pharmaceutical ointments, creams, and pastes. Ointment bases vary in viscosity and solubility and are classified as oleaginous, emulsifiable, emulsified, and water-soluble.

Ointments are formed by dissolving or suspending a drug in a semisolid base. Although the term "ointment" is sometimes used specifically for drug-containing oleaginous bases, emulsion bases (creams), water-soluble bases, and pastes are also considered ointments. *Pastes,* which contain large quantities of insoluble solids such as zinc oxide or talc, are stiffer than other types of ointments and are used often as protective barriers or absorbents.

Hydrocarbon-based ointments are typically hydrophobic, greasy, and occlusive, and inhibit the evaporation of water from the skin. In addition to this moisturizing effect, oleaginous ointments have emollient and protective qualities. When applied to intact skin, ointments form a thin film that is maintained at the application site for an extended period, providing prolonged delivery of the active ingredient.

Oleaginous ointment bases include yellow and white petrolatums, which are mixtures of liquid and solid hydrocarbons derived from petroleum (→ Waxes, Chap. 4.2). Natural waxes (e.g., beeswax) or synthetic waxes (e.g., cetyl esters wax) may be added to oleaginous bases to enhance stiffness; vegetable oils (e.g., olive oil and cottonseed oil) can be incorporated as softeners. Less commonly, vegetable oils and animal fats are themselves used as ointment bases.

Fusion of solid waxes or polyethylene resin with mineral oil produces hydrocarbon ointments that allow for better diffusion and release of drug. Ointments containing silicone oils are excellent emollients but, like hydrocarbon oils, are poor solvents for many drugs.

Emulsifiable bases share many of the qualities of oleaginous bases, but differ in their capacity to absorb water. Emulsifiable bases incorporate large quantities of water, forming water-in-oil (w/o) emulsions whose external phase retains the characteristics of an oleaginous film. Absorption bases of this type, such as hydrophilic petrolatum and anhydrous lanolin, contain emulsifying agents (e.g., cholesterol) and long-chain alcohols (e.g., stearyl alcohol and lanolin alcohols), which aid the hydration process.

Creams are semisolid emulsions that are more fluid and more easily spread than ointments. Emulsion bases include w/o emulsions, which absorb small quantities of water, and water-washable oil-in-water (o/w) emulsions.

Like oleaginous and emulsifiable bases, w/o emulsions are greasy and difficult to remove from the skin. They are effective emollients, but somewhat less occlusive than oleaginous bases. Examples of w/o emulsion bases are lanolin and petrolatum – rose water ointment. The latter is sometimes called "cold cream" because of the cooling effect produced by release and evaporation of the aqueous external phase when the cream is applied to the skin.

Water-washable o/w emulsions are commonly referred to simply as "creams." Because they are nonocclusive, nongreasy, and easily washed from the skin, these creams have relatively high esthetic appeal and patient acceptance.

Typically, creams have (1) an oleaginous internal phase composed of petrolatum-based hydrocarbons and high molecular mass alcohols or fatty acids, (2) an aqueous external phase often containing preservatives, humectants, and buffers, and (3) one or more emulsifying agents.

Commonly used emulsifiers include anionic surfactants (e.g., sodium lauryl sulfate and triethanolamine stearate) and nonionic surfactants (e.g., ethylene oxide derivatives). Cationic detergents, such as quaternary ammonium salts, are more irritating and somewhat less useful.

Because most of the aqueous phase evaporates when a cream is applied to the skin, a nonvolatile cosolvent, such as propylene glycol, is usually incorporated to assure drug solubilization in the oleaginous film.

Drug solubility may be further enhanced by water-soluble ointment bases containing liquid and waxy solid poly(ethylene glycol). These bases are nonocclusive, nonirritating, and washable from the skin. Nonetheless, bioavailability from water-soluble bases may not be improved over hydrocarbon bases because maximization of drug solubility can be offset by insufficient stratum corneum hydration.

Aqueous gels or jellies represent another class of water-soluble ointment bases in which a liquid internal phase is immobilized within a three-dimensional matrix. This system is formed by colloidal dispersions of small inorganic or large organic molecules in aqueous media. Gels can also be formed by semisolid w/o or o/w microemulsions, which may provide better solubilization of drug after application to the skin. Gelling agents include nonionic or anionic cellulose derivatives (e.g., sodium carboxymethylcellulose), acidic carboxy vinyl polymers, and other hydrophilic colloids, such as magnesium aluminum silicate, sodium alginate, and tragacanth. Some gelling agents can also be used with nonpolar solvents.

Although semisolids are an invaluable class of topical delivery system, liquid and solid dosage forms are also widely used for topical therapy. Liquid preparations applied to the skin include lotions and solutions. *Lotions* are generally aqueous preparations that spread easily on the skin. They may contain suspended solids or emulsified liquids. Topical *solutions* often contain aqueous vehicles with cosolvents, e.g., alcohol, acetone, and poly(ethylene glycol), as required for drug solubilization. Propylene glycol can also be used as a solvent, particularly in topical solutions of corticosteroids.

Topical agents are also formulated into *powders.* For example, antifungal agents, such as miconazole nitrate [*22832-87-7*], are widely used in powder form as an adjunct to treatment with antifungal solutions, creams, and ointments.

2.2. Percutaneous Absorption

Topically applied drugs often cannot reach disease sites in the epidermis or dermis in sufficiently high concentrations to exert a therapeutic effect [1, 2]. The stratum corneum is the major barrier to skin penetration. The interaction of the stratum corneum with the applied drug and vehicle largely determines the rate and extent of percutaneous absorption.

The two major processes in percutaneous absorption are *intraphase diffusion* and *interphase partitioning* [3]. These occur consecutively and repeatedly as the drug passively leaves the vehicle and permeates the various layers of the skin. The higher the diffusion and partition coefficients of a drug, the greater is the drug's ability to penetrate the skin. Drugs move from the vehicle to the viable epidermis primarily through the stratum corneum, but may also gain entry through pilosebaceous follicles or sweat ducts.

The rate of penetration is also directly proportional to the rate of vehicle release of drug, concentration of applied drug, surface area, duration of application, and degree of stratum corneum hydration. Percutaneous absorption is inversely proportional to stratum corneum thickness and, therefore, may vary, depending on anatomical site.

Transfer of drug from the vehicle to the skin surface, the initial step in percutaneous absorption, is determined by drug diffusion through the vehicle and partitioning into surface skin tissue (e.g., stratum corneum or sebum).

Solubility is a crucial factor in release of drug from the vehicle. First, dissolution of the drug in the vehicle is a prerequisite for its diffusion through the vehicle to the skin surface. Second, the relative solubility of the drug in the vehicle and skin surface is a major determinant of the partition coefficient between the two phases.

The vehicle – skin surface partition coefficient is an important factor in percutaneous absorption [4]. Increasing the lipid solubility of a drug increases its penetration into the stratum corneum and often enhances percutaneous absorption.

After reaching the skin surface, the drug must diffuse across the stratum corneum (or through the follicle) before moving relatively easily through underlying tissue. Drug diffusion through the stratum corneum is generally slow and represents the rate-limiting step in percutaneous absorption. Large lipophilic drugs, such as the corticosteroids, may be preferentially absorbed by the transfollicular route because of their relatively high diffusion rates in the sebum compared to that in the stratum corneum.

Drug transport is driven by a concentration gradient that is maintained by rapid removal of drug by the systemic circulation via dermal capillaries. The systemic circulation is often referred to as a "sink" for the drug.

2.3. Vehicles

A drug's formulation may have a significant impact on its topical potency, given the critical role of vehicle release of drug and the stratum corneum – vehicle partition coefficient in percutaneous absorption. Vehicles may enhance drug penetration by influencing solubility and release or by altering stratum corneum resistance [5].

Oleaginous vehicles, including petrolatum-based ointments and, to a lesser extent, water-in-oil emulsions, form an occlusive barrier on the skin, preventing the evaporation of sweat and insensible water loss and thereby promoting hydration of the stratum corneum. Hydration softens the stratum corneum, expanding the protein matrix by a "sponge" effect and increasing drug penetration.

Release of a drug from the vehicle is maximal from a saturated solution. This assures that a highly soluble drug is not preferentially retained in the vehicle. Among the vehicle factors that may affect solubility are pH, particle size, and choice of solvent.

The important role of drug solubility, and, therefore, choice of solvent, in determining drug release, penetrability, and bioavailability was demonstrated by numerous studies of topical corticosteroids. The solubility of corticosteroids is greatly enhanced by adding cosolvents, such as propylene glycol or dimethylsulfoxide (DMSO), to aqueous vehicles. For example, the

release of fluocinonide (0.025 wt %) from propylene glycol – water gels is greatest from vehicles containing exactly enough propylene glycol to completely dissolve the drug [6]. Excess propylene glycol reduces the bioavailability of fluocinonide by decreasing the partition coefficient of the drug between the skin and the vehicle. Similarly, maximal penetration cannot be attained from vehicles containing insufficient solubilizer.

Organic solvents, such as acetone or ethanol can also enhance the penetration of corticosteroids from topical solutions; however, the irritation caused by these solvents limits their use in topical drug therapy. Oil-in-water emulsions that contain castor oil also favor the absorption of corticosteroids.

Modifications in the vehicle after application to the skin can affect drug bioavailability. For example, adding a volatile solvent such as isopropanol to the vehicle substantially increases the penetration of corticosteroids from nonvolatile solvents, such as propylene glycol or isopropyl myristate [7]. Rapid evaporation of isopropanol after application to the skin increases the drug concentration in the nonvolatile component.

In addition to their effect on solubility, solvents may also influence the barrier properties of the skin. Propylene glycol and aprotic solvents, such as DMSO, dimethylacetamide (DMA), and dimethylformamide (DMF), interact with the stratum corneum to increase the permeability of the skin to various compounds, including glucocorticosteroids and antibiotics.

Although the mechanism of their effect is not clearly defined, studies suggest that DMSO and related compounds induce reversible changes in the otherwise impenetrable protein matrix of the stratum corneum [8]. Expansion of the stratum corneum and creation of channels by incorporation of large quantities of solvent may contribute to enhanced drug permeation. Among the drawbacks of these agents are irritation, odor, and a potential for systemic absorption and toxicity.

Relatively low concentrations of the odorless, nonirritating solvent 1-dodecylazacycloheptan-2-one [*59227-89-3*] (N-0252, Azone) have been shown to increase the penetration of antibiotics, corticosteroids, and fluorouracil [9].

3. Classification of Drugs

A broad range of pharmacological agents are employed in the treatment of skin diseases. Some drugs, such as the antiacne agent tretinoin, have been developed specifically for dermatological disorders. Glucocorticosteroids and other classes of drugs are widely used in systemic diseases, but have a unique role in cutaneous disease. This chapter focuses on the major categories of dermatotherapeutic agents to provide an overview of the most common cutaneous disorders.

3.1. Anti-Inflammatory Agents

Inflammation is a complex host response to cellular injury associated with many cutaneous disorders (→ Anti-inflammatory–Antirheumatic Drugs). Cutaneous inflammation is often mediated by immunologic mechanisms, including antigen-dependent mast cell release of histamine, leukotrienes, chemotactic factors, and other vasoactive and smooth muscle contracting substances. Inflammation can also be produced by prostaglandins and kinins [10].

Eczematous dermatitis, for example, represents a group of inflammatory skin disorders that develop in response to various exogenous or endogenous stimuli. The types of eczema include seborrheic, atopic, stasis, infectious eczematoid, and allergic or irritant contact dermatitis.

Eczema is often mediated by immune mechanisms. *Allergic contact dermatitis* is a delayed hypersensitivity reaction to an external substance (e.g., nickel, rubber, or poison ivy) in previously sensitized individuals. *Photoallergic contact dermatitis,* in which photoactivation of the compound or hapten (e.g., halogenated salicylanilides) is followed by conjugation with skin proteins and results in the formation of a complete antigen, is associated with a cell-mediated immune response similar to that in contact allergy. In contrast, *nonallergic contact dermatitis* (irritation) may be elicited immediately after initial exposure to primary chemical or mechanical irritants.

Atopic dermatitis is a common form of chronic eczema that often develops in genetically predisposed children in conjunction with hay fever or asthma. The underlying cause is

not known, but it may be related to alteration in cellular and humoral immunity mediated by cyclic nucleotides or to autonomic nervous system function [11].

Immediate-type hypersensitivity reactions may also lead to inflammation. *Urticaria* or hives, characterized by pruritic, erythematous areas of localized edema known as wheals, may result from IgE-dependent mast cell degranulation on exposure to certain foods, drugs (e.g., penicillin), or inhaled allergens, or to physical agents, such as cold, sunlight, or pressure.

Although the pathophysiologic characteristics of eczematous dermatoses may vary, the *clinical features* are similar. These include erythema, blisters, crusting, and pruritus in acute conditions and epidermal thickening, accentuated skin lines, and dryness in chronic stages. Thus, *symptomatic treatment* of eczema is relatively uniform and often includes systemic antihistamines for pruritus and topical or systemic anti-inflammatory drugs. Adjunctive therapy may include topical antipruritics, occlusive emollients, and baths. Many of the same treatment modalities are employed in urticaria.

The following four classes of drugs are frequently used in the symptomatic treatment of inflammatory disorders and, as indicated, may also benefit various other cutaneous disorders.

Antihistamines (→ Antiallergic Agents, Chap. 2). Histamine [*51-45-6*] is a substituted imidazole formed by enzymatic decarboxylation of the amino acid histidine. It is primarily synthesized and stored in mast cells and basophils. One of several chemical inflammatory mediators of immediate hypersensitivity reactions, histamine is actively secreted from IgE antibody-bound mast cells in response to a specific antigen. Histamine release is triggered by influx of calcium ions, which initiates a series of intracellular changes mediated by membrane and cytosolic signal transducing pathways [12, 13].

Histamine has a wide range of *physiologic effects* mediated through four distinct G protein-coupled receptors, H-1, H-2, H-3, and H-4 [14]. The H-1 and H-2 receptor subtypes are found in skin. Both of these receptors mediate the vasodilatory effects of histamine. H-1 receptors participate in histamine-induced increases in capillary permeability and edema. These responses are manifested in the skin as localized erythema and whealing (urticaria).

Histamine-induced stimulation of sensory nerve endings, predominantly an H-1 effect, completes the so-called "triple response" to histamine. This action causes axon-reflex vasodilation characterized by an erythematous flare. Nerve stimulation also accounts for histamine-induced pruritus and pain.

Widespread release of histamine in the body can cause extensive vasodilation and a marked fall in blood pressure. This response, combined with vascular fluid leakage, can lead to a condition resembling surgical or traumatic shock.

Extravascular smooth muscle contraction is H-1-mediated and leads to bronchoconstriction and increased force of heart contraction. In some cases, activating H-2 receptors will relax smooth muscle. In the heart, almost all of the effects of histamine on cardiac muscle, such as increases in heart rate and force of heart contraction, are through H-2 receptors. Gastric secretion is stimulated by histamine at H-2 receptors and can be attenuated by H-2 receptor antagonists [15]. H-4 receptors, present on bone marrow-derived secretory cells, play a role in inflammation and pruritus [16].

Systemic H-1 antihistamines competitively and reversively bind to H-1 receptors. These antihistamines belong to six chemical classes and all share in common a substituted tertiary amino group. The older H-1 compounds are effective histamine blockers but they also possess varying degrees of anticholinergic, antiemetic, and sedative properties. More recent H-1 blockers have been designed so as not to penetrate the blood-brain barrier and thus cause little or no sedation. These newer compounds also lack anticholinergic activity.

The original H-1 antihistamines, such as tripelennamine [*91-81-6*], pyrilamine [*91-84-9*], diphenyhydramine [*58-73-1*] and chlorpheniramine [*132-22-9*], have been widely used for symptomatic relief of histamine-induced pruritus and urticaria [17]. Antihistamines are generally not used topically because of their potential to induce contact or photocontact dermatitis. The antipruritic effects of oral H-1 antihistamines in eczematous dermatitis (e.g., atopic dermatitis) or nonallergic pruritic disorders may be primarily mediated by a sedative action. The nonsedating H-1 antihistamines, including lo-

ratadine [*79794-75-5*] and fexofenadine [*83799-24-0*], are useful for allergic rhinitis and chronic urticaria, but their effectiveness in dermatitic and pruritic conditions continues to be investigated.

Studies of H-2 blockers in the treatment of pruritus have produced mixed results. Hydroxyzine [*68-88-2*], a piperazine H-1 blocker, is a frequent choice for systemic treatment of pruritus and appears to be one of the most effective antihistamines for suppression of whealing. With the exception of cyproheptadine [*129-03-3*], H-1 antihistamines appear less effective in physical urticarias than in other forms of urticaria.

The H-2 blocker cimetidine [*51481-61-9*] has been used together with H-1 antihistamines for treatment of chronic urticaria unresponsive to H-1 therapy. Evidence exists that such combinations are more effective than the use of H-1 blockers alone, although cimetidine may worsen symptoms by blocking feedback inhibition of histamine release. Likewise, diminished T-cell suppression by cimetidine may cause exacerbation of delayed hypersensitivity.

Cromolyn sodium [*15826-37-6*] (→ Antiallergic Agents, Chap. 3), a water-soluble bis(chromone) derivative, antagonizes histamine through stabilization of the mast cell membrane rather than receptor blockade. This agent may be used orally in mastocytosis, food allergies, and dermatitis herpetiformis. Topical formulations may be beneficial in atopic dermatitis, atopic keratoconjunctivitis, and various ulcerations.

Doxepin [*1668-19-5*] (→ Psychopharmacological Agents), a tricyclic antidepressant, is a potent H-1 antagonist with mild H-2 blocking activity. Intradermally administered doxepin suppressed whealing in human skin, and topical applications were shown to be possibly effective for the control of pruritus [18]. In a double-blind study, oral doxepin was significantly more effective and less sedative than diphenhydramine [*58-73-1*] in the treatment of chronic urticaria. When tested topically, doxepin was more effective than placebo in reducing pruritus in patients with atopic dermatitis [19]. Thus, compounds in this class may possibly prove useful for controlling allergic skin reactions.

Nonsteroidal Anti-Inflammatory Drugs. These drugs are widely used for treating internal inflammation and pain but may also have some utility for treating cutaneous inflammation. Drugs in this class inhibit the production of eicosanoids, inflammatory mediators derived primarily from arachidonic acid [20]. The major eicosanoid-producing enzymes are cyclooygenases (COX) and lipoxygenases (LOX). Two enzymes, COX-1 and COX-2, produce prostaglandins. Most traditional NSAIDs, such as acetylsalicylic acid [*50-78-2*] and indomethacin [*53-86-1*], are non-selective and inhibit both COX-1 and COX-2. Gastrointestinal and renal toxicity by NSAIDS is the result of inhibiting COX-1, an enzyme needed for normal physiological processes in these two organ systems. COX-2-selective inhibitors were developed to decrease the risk of gastrointestinal ulceration.

Lipoxygenases produce several forms of lipid hydroxy acids, most notably hydroxyeicosatetraenoic acids (HETES) and leukotrienes. Inhibitors of 5-lipoxygenase, such as zilueton [*111406-87-2*], prevent the synthesis of leukotrienes. The leukotriene antagonists zafirlukast [*107753-78-6*] and montelukast [*158966-92-8*] block the action of leukotrienes at their receptors.

Studies in animals and humans show that prostaglandins and leukotrienes are produced in various skin inflammatory conditions, including ultraviolet radiation-induced erythema, contact dermatitis and psoriasis. Indomethacin has been shown to partially inhibit erythema induced by UV-B radiation (290 – 320 nm) when administered topically [21 – 23]. In contrast, topical corticosteroids were found to be inactive. Topical bufexamac [2438–72–4] has demonstrated some efficacy in steroid-responsive dermatoses other than psoriasis.

Glucocorticosteroids (→ Hormones, Chap. 4). Systemic and topical glucocorticosteroids are widely used to relieve inflammatory and pruritic manifestations of various acute and chronic skin diseases.

Glucocorticoids are 21-carbon pregnane derivatives that are synthesized in the adrenal cortex. Biological activity is dependent on the presence of a double bond at the 4 – 5 position, two keto groups (positions 3 and 20), and three hydroxy groups (positions 11, 17, and 21). Structural modification of the steroid nucleus greatly influences therapeutic potency as a result

of changes in pharmacokinetic parameters, such as absorption, protein binding, and metabolism. For example, fluorination at the 9-position, addition of a 1,2-double bond, esterification of the 17- or 21-hydroxyl groups, and inclusion of an acetonide group at positions 16 and 17 greatly increase anti-inflammatory activity [24, 25]. Replacement of the 21-hydroxyl group with chlorine results in a highly effective class of corticosteroids; these synthetic steroids, which have two or more halogen groups, are the most potent of the synthetic glucocorticoids [26].

Other structural modifications of the steroid nucleus has led to development of moderately potent glucocorticoids with less propensity to cause adverse effects such as skin atrophy. These include mometasone furoate [*83919-23-7*], a 21-chloro compound with a 17-furoate moiety, and prednicarbate [*73771-04-7*], which is a non-halogenated, 17,21-diester. These agents either have low rates of transdermal absorption or are rapidly metabolized to compounds with minimal glucocorticoid activity.

Glucocorticoids inhibit inflammation by various mechanisms. Like other steroid hormones, they initiate their biological effects by binding to intracellular receptors. Once bound to the receptor, the glucocorticoid – receptor complex translocates to the nucleus. This complex then interacts alone or with other proteins to attenuate or enhance expression of numerous genes. Consequently, almost all aspects of the inflammation process are diminished by glucocorticoids. These include reduced leukocyte infiltration into tissues, reduced expression of cytokines, decreased expression of eicosanoid-generating enzymes (phospholipases, cyclooxygenases) and proteolytic enzymes. This in part accounts for the ability of glucocorticoids to suppress cell-mediated immune responses. In skin, glucocorticoids cause vasoconstriction and inhibit proliferation of keratinocytes.

Systemically administered glucocorticoids decrease the number of polymorphonuclear leukocytes (PMNS) at sites of tissue inflammation, as reflected by an increase in circulating PMNS. These changes are accompanied by decreases in circulating lymphocytes, monocytes, and eosinophils [27, 28].

Corticosteroids also exert their anti-inflammatory effect by inhibiting T-lymphocyte and B-lymphocyte function and reduce the immune responsiveness and microbicidal activity of macrophages. Although corticosteroids inhibit antibody synthesis and related B-cell functions, they have a more pronounced effect on T-cell-mediated, delayed hypersensitivity responses. In addition, corticosteroids depress antigen-induced proliferation of T-cells and cytokine release and interfere with cytokine activities.

Topical glucocorticosteroids are particularly beneficial in inflammatory skin disorders, such as atopic and contact dermatitis, eczema, seborrheic dermatitis, and psoriasis [29]. Daily applications are generally employed to limit the possibility of tachyphylaxis. Moreover, steroids apparently are slowly released from the stratum corneum for several days after a single application.

Choice of vehicle is determined by lesion type and drug solubility and is an important factor in epidermal penetration of glucocorticoids [30]. Hydration of the stratum corneum by ointment bases may enhance steroid penetration and may be useful in dry, scaling lesions. Occlusion of the skin with an impermeable plastic film has been shown to increase steroid penetration by ca. 10-fold. Glucocorticosteroids are highly soluble in gel vehicles and are equally effective in gel or ointment bases.

The anti-inflammatory potency of glucocorticosteroids closely parallels their capacity to induce gluconeogenesis and protein catabolism. Thus, skin atrophy may result from either topical or systemic corticosteroid administration and appears to be related to inhibition of collagen synthesis. In addition to epidermal thinning and stria formation, possible adverse effects of potent halogenated topical steroids include stellate pseudoscarring, purpura, telangiectasia, acneiform and rosacea-like eruptions, and perioral dermatitis.

Glucocorticosteroids are also administered by intralesional or intramuscular injection. Among the skin conditions responsive to intralesional steroids are acne vulgaris, lichen planus, psoriasis, localized eczema, keloids, and sarcoidosis. The intramuscular route is used extensively for various acute and chronic dermatoses, but may be associated with increased risk of steroid toxicity, especially alteration of the hypothalamic – pituitary – adrenal axis.

Similarly, systemic glucocorticosteroids are important in a broad range of acute and chronic disorders (e.g., allergic contact dermatitis, atopic dermatitis, lichen planus, and herpes zoster) [31]. Their use is limited by the risk of hypothalamic – pituitary – adrenal axis suppression, cushingoid symptoms, and a host of other potential metabolic, hematologic, and infectious complications.

Steroids may be administered in single daily doses or on alternate days to minimize the potential toxicity of long-term maintenance therapy. Although single-dose therapy may be an alternative to divided doses in many acute dermatoses, achieving adequate initial control of inflammation by using alternate-day regimens may be difficult. Likewise, high-potency topical steroids are generally used for initial therapy and are replaced by less potent agents when appropriate. Cessation of steroid therapy or conversion from daily to alternate-day therapy requires careful modulation of dosage to avoid rebound flare of disease or adrenal insufficiency.

Calcineurin Inhibitors. Calcineurin, a calcium-dependent phosphatase enzyme, is activated by elevated intracellular calcium. Activated calcineurin triggers the synthesis and release of the T-lymphocyte growth stimulator, interleukin-2. Compounds with binding affinity for immunophilin proteins form a complex that binds to calcineurin and inhibits its activation. Calcineurin inhibitors thus inhibit IL-2 production and T-lymphocyte proliferation, and cause immune suppression [32].

The topically applied calcineurin inhibitors tacrolimus [*109581-93-3*] and pimecrolimus [*137071-32-0*] are used in patients with moderate to severe cases of atopic dermatitis who are unresponsive to conventional treatments [33]. Unlike topical glucocorticoids, these agents do not cause skin thinning. Short-term side effects of calcineurin inhibitors are mainly local, consisting of burning and irritation at application sites. Practitioners have been alerted to possible long-term effects of cancer, however these warnings are based on the compounds' immunosuppressive properties and findings from animal toxicity studies.

Topical Antipruritics, Emollients, and Baths. Lotions containing antipruritics, such as menthol [*1490-04-6*], phenol [*108-95-2*], camphor [*76-22-2*], and astringents, such as zinc oxide [*1314-13-2*] and calamine [*8011-96-9*], are often used for symptomatic treatment of acute eczema and urticaria. Wet dressings containing aluminum acetate [*139-12-8*] solution or bath preparations containing colloidal solids, such as oatmeal or *sulfur* [*7704-34-9*], may also be beneficial.

Antipruritic tar baths and emollient oil baths are helpful for chronic lesions. Occlusive emollient creams or ointment bases, including anhydrous lanolin [*8006-54-0*] and petrolatum [*8009-03-8*], decrease evaporative loss of water from the skin surface and may be applied to relieve dryness. Urea [*57-13-6*] and lactic acid [*50-21-5*] are frequently incorporated into these emollient bases to enhance moisture retention and soften the stratum corneum.

Local anesthetics, including the ester derivative benzocaine [*94-09-7*], depress the conduction of nerve impulses and may provide relief of pain and itching. Their use in eczema is limited because they may cause contact sensitization.

3.2. Antiacne Agents

Acne vulgaris is a common dermatological disorder characterized by noninflammatory comedones (open or closed) and inflammatory papules, pustules, and cysts.

Therapy may be directed at one or more of the following pathophysiologic processes associated with acne: increased sebum production, hyperkeratinization, *Propionibacterium acnes* (*P. acnes*) proliferation, and inflammation.

The initial *stimulus for acne development* appears to be an alteration in the normal pattern of follicular epithelial cell differentiation known as abnormal follicular keratinization [34]. The cause of this defect is unknown, but may relate to hormonal changes, increased sebum production, or bacterial colonization of the hair follicles. The altered keratinization process is characterized by production of a mass of tightly coherent keratinocytes and results in blockage of sebum flow, overgrowth of *P. acnes*, and follicular dilation to form microcomedones. Breakdown of the follicular wall initiates the inflammatory phase of acne, which is mediated by bacteria-derived enzymes and chemotactic factors [35].

Consequently, therapeutic agents that reverse the underlying keratinization defect are particularly effective in clearing microcomedones and preventing their formation. They also indirectly prevent inflammatory lesions. Antibacterial, anti-inflammatory, and sebostatic agents have a pronounced effect on inflammatory lesions, but do not correct the underlying abnormal follicular keratinization. Topical keratolytic or peeling agents, including sulfur, resorcinol [*108-46-3*], and salicylic acid [*69-72-7*], do not prevent lesion formation and, therefore, provide only temporary clearing.

Comedolytic Agents. The *retinoids,* including vitamin A and its derivatives, modify the altered epithelial replication process characteristic of acne, psoriasis, ichthyosis, and other keratinizing dermatoses [36].

In a study comparing the antikeratinizing effects of topical antiacne agents in rhino mouse skin, only the retinoids produced substantial reduction in the size of utriculi (keratinized follicles) [37]. Of the retinoids, all-*trans*-retinoic acid [*302-79-4*] (tretinoin, → Vitamins, Chap. 2.1) exhibited the greatest comedolytic potency. Tretinoin also gave greater reduction in comedones than motretinide [*56281-36-8*] in clinical studies [38]. Orally administered retinoids showed less comedolytic activity than topical retinoids in an earlier study using the rhino mouse model [39]. Oral tretinoin had more than twice the potency of oral 13-*cis*-retinoic acid [*4759-48-2*] (isotretinoin).

Tretinoin is a natural retinoid metabolite of vitamin A that binds to cellular retinoic acid binding proteins in the cytoplasm and receptors in the nucleus. The nuclear receptors are mechanistically considered the site of action of tretinoin. Tretinoin activates the three members of the retinoic acid (RAR) nuclear receptors (RARα, RARβ, RARγ) which act to modify gene expression, and subsequent protein synthesis, to account for its beneficial clinical effects [40].

Tretinoin is perhaps the most effective topical agent for treatment and prevention of comedonal and inflammatory acne. Tretinoin decreases horny cell cohesiveness and stimulates epidermal cell turnover, thereby removing existing microcomedones and preventing their reformation. Tretinoin may enhance resolution of inflammatory lesions by increasing blood flow. Moreover, its ability to reduce stratum corneum thickness and to potentiate the absorption of other topical compounds makes tretinoin a potentially valuable component in combination acne therapy.

Synthetic receptor-selective topical retinoids are also available to treat acne vulgaris. Adapalene [*106685-40-9*], a naphthoic acid derivative, and tazarotene [*118292-40-3*], an acetylenic retinoid, are selective for RARβ and RARγ [41, 42]. Tazarotene does not bind to the RARs but is metabolized by an esterase to the active form, tazarotenic acid, which binds to RARs and activates them.

Antibacterial Agents. The oxidizing agent benzoyl peroxide [*94-36-0*] is commonly used in the topical treatment of acne. Benzoyl peroxide possesses both comedolytic and antibacterial properties, but the latter is believed to be primarily responsible for its therapeutic efficacy. Release of free-radical oxygen by benzoyl peroxide decreases the levels of *P. acnes* and skin surface lipids, leading to reduction in inflammatory lesions. Benzoyl peroxide also reduces inflammatory lesions via stimulation of blood flow and may have a sebostatic effect. Acetone or water-based gel formulations may allow for enhanced penetration and efficacy of benzoyl peroxide. The combination of benzoyl peroxide with erythromycin [*114-07-8*], a macrolide antibiotic (→ Antibiotics, Chap. 3.5.2), is more effective than either ingredient alone in reducing inflammatory lesions.

Oral tetracyclines or erythromycin are the drugs of choice for treatment of moderate inflammatory acne, with cotrimoxazole (trimethoprim [*738-70-5*] plus sulfamethoxazole [*723-46-6*]) occasionally used in refractory patients. Topical antibiotics, including erythromycin [*114-07-8*], clindamycin [*18323-44-9*] (→ Antibiotics, Chap. 4), tetracycline [*60-54-8*] (→ Antibiotics, Chap. 4), and meclocycline [*2013-58-3*], are generally recognized as safe and effective alternatives to long-term systemic therapy [43, 44].

The mechanism of action of oral and topical antibiotics in acne is not fully understood. Previously, oral antibiotics were shown to suppress follicular bacterial colonization and production of free fatty acids. Later studies suggested that

inhibition of bacterial metabolism (e.g., lipase production) may be the primary mode of action of topical antibiotics [45]. Topical antibiotics also possess anti-inflammatory properties mediated in part by inhibition of neutrophil chemotaxis [46].

Azelaic acid [*123-99-9*] (→ Dicarboxylic Acids, Aliphatic), a naturally occurring saturated dicarboxylic acid, is topically effective in treating mild to moderate inflammatory acne vulgaris. The exact mechanism is not known but it has antimicrobial activity against *P. acnes* and *S. epidermidis* with normalization of keratinization.

Systemic Retinoids. Oral isotretinoin provides excellent therapeutic results and long-term remissions in patients with severe cystic acne [47]. Its use is limited by a high incidence of mucocutaneous (xerosis, cheilitis) and systemic adverse effects (vertebral hyperostoses, hypertriglyceridemia) and because it is teratogenic in humans. Women of child-bearing age must have a pretreatment pregnancy test and be ensured of adequate contraception for the duration of therapy.

The effects of isotretinoin in acne are related primarily to marked suppression in sebum production that results from a direct effect on the sebaceous gland [48]. The decrease in sebum production is accompanied by reduction in bacterial flora [49]. Less clearly characterized is the inhibitory effect of isotretinoin on follicular hyperkeratinization [50]. Isotretinoin may also exert an anti-inflammatory effect with inhibition of neutrophil function.

Hormones. Elevated levels of androgens are known to cause acne in some women. High levels of androgens lead to increased sebum production and follicular hyperkeratosis. Oral contraceptives can reduce androgen levels and are effective in treating acne in women. This therapy for acne targets sex hormone binding globulin (SHBG) and free testosterone [*58-22-0*]. A low dose oral contraceptive containing norgestimate [*35189-28-7*] and ethinyl estradiol [*57-63-6*] (→ Contraception, Chap. 4.1) is a safe and effective treatment of acne with efficacy similar to benzoyl peroxide and topical or systemic antibiotics [51]. This combination increases SHBG and decreases free testosterone in healthy women. Norgestimate binds to progestin receptors and has low affinity for androgen receptors and SHBG. Ethinyl estradiol may have antiandrogenic effects by suppressing the secretion of gonadotropins and inhibiting the production of ovarian androgens.

Spironolactone is an antiandrogen that blocks the binding of androgen to the androgen receptor and is useful in treating recalcitrant acne in women. Combinations of synthetic estrogens with nonandrogenic progestogens or the synthetic antiandrogen cyproterone acetate [*427-51-0*] (→ Hormones, Chap. 3.6.3) have been used successfully to treat female acne patients with acne conglobata.

Anti-Inflammatory Agents. Short-term therapy with oral corticosteroids (e.g., prednisone [*53-03-2*]) in conjunction with maintenance therapy with sulfones (e.g., dapsone [*80-08-0*]) is sometimes used in patients with severe acne conglobata. Dapsone has been shown to stabilize lysosomes and interfere with neutrophil function. Intralesional injections of triamcinolone acetonide [*76-25-5*] are frequently used for patients with severe scarring. Ibuprofen [*15687-27-1*] has also shown some efficacy in diminishing inflammatory acne.

3.3. Antipsoriatics

Psoriasis is a common, chronic skin disorder of variable and unpredictable course. It is characterized by accelerated epidermal cell turnover and inflammation to produce elevated, erythematous plaques covered with silver scale. The underlying cause of the disease is unknown, but various environmental, genetic, and immunologic factors influence its expression. A familial predisposition to psoriasis is evidence of one or several genes accounting for its expression. A dysregulation in the immune system, primarily with T-lymphocytes, is considered to be the fundamental mediator of the epidermal and inflammatory changes in the psoriatic lesion [52]. External stimuli, such as infectious disease, skin trauma, or psychological stress are known triggers of psoriatic plaque formation.

Topical therapy is most effective for short-term use in mild psoriasis and may be combined with ultraviolet radiation or systemic agents in extensive or resistant cases. Many of the ther-

apeutic modalities for severe psoriasis (photochemotherapy, phototherapy, and cytotoxic therapy) directly suppress immune cell activity. Some of these agents also diminish epidermal hyperplasia by inhibiting DNA synthesis and mitosis.

Topical Agents. Occlusive emollients, such as petrolatum and mineral oil [*8012-95-1*], are frequently used alone or in combination with keratolytic agents, such as salicylic acid [*69-72-7*] and urea [*57-13-6*], to facilitate hydration and removal of hyperkeratotic plaques.

The topical synthetic vitamin D analog, calcipotriene [*112965-21-6*] (calcipotriol, → Vitamins, Chap. 3.3) is frequently used for treating moderate plaque psoriasis. This agent acts to enhance keratinocyte differentiation and also exhibits immunomodulatory activity [53]. The major local side effect of calcipotriene is skin irritation; unlike corticosteroids, calcipotriene does not cause skin atrophy. Adverse systemic effects of topical calcipotriene are limited due to its rapid metabolic inactivation within 24 h after it is applied.

Potent topical corticosteroids (e.g., clobetasol propionate [*25122-46-7*] and halobetasol propionate [*66852-54-8*]) are frequently administered intermittently in more severe cases of psoriasis because of their vasoconstrictive, antimitotic, and anti-inflammatory effects. Glucocorticoids also have significant inhibitory effects on immune cell activation. Intralesional steroids are also used in psoriasis. Long-term use of corticosteroids results in a loss of effectiveness and an increased risk of toxicity.

Coal tar preparations have long been used safely and effectively in psoriasis. Coal tar is a complex and variable mixture of at least 10 000 compounds; it contains many phenols, bases, and polyaromatic hydrocarbons, including several potent photosensitizers and carcinogens. Although its mechanism of action in psoriasis is not well-defined, coal tar inhibits DNA synthesis and may also have antipruritic and vasoconstrictive properties. Coal tar is commonly used in conjunction with ultraviolet radiation as described below (see page 12).

Anthralin [*480-22-8*] (dithranol), a synthetic derivative of the natural antipsoriatic agent chrysarobin, depresses DNA synthesis and epidermal replication by interfering with polyamine production. It may also exert anti-inflammatory and immunosuppressive effects. Like coal tar, anthralin may cause skin irritation and staining.

A synthetic retinoid, tazarotene, is topically effective for moderate psoriasis. Retinoic acid [*302-79-4*] has also been applied topically in psoriasis, as have several cytotoxic agents, including the sulfur and nitrogen mustards (e.g., mechlorethamine hydrochloride [*55-86-7*]).

Phototherapy. Ultraviolet radiation is well-known for its therapeutic value in psoriasis. Its biologic effects, thought to account for its efficacy in psoriasis, are wide-ranging; it can suppress the immune system and inhibit mitosis. These properties are primarily attributable to the UV-B wavebands (290 – 320 nm), although relatively high doses of UV-A (320 – 400 nm) may also be beneficial. UVB phototherapy is often used for patients who either do not respond to topical antipsoriatic drugs or for those who find topical treatment inconvenient.

Ultraviolet radiation is widely used in combination with anthralin and/or coal tar in the treatment of psoriasis. The *Goeckerman regimen* generally consists of multiple daily applications of crude coal tar ointment, a daily tar bath, and subsequent exposure to UV-B and UV-A radiation.

Whether or not the photosensitizing action of coal tar is of therapeutic relevance in psoriasis is unclear. Although the action spectrum of coal tar phototoxicity is in the UV-A range and the inhibitory action of coal tar on DNA synthesis is enhanced by UV-A radiation, coal tar is not photosensitive at commonly used doses of UV-A. Moreover, UV-B radiation–coal tar appears to be more effective than UV-A radiation–coal tar in psoriasis. Other studies suggest that the contribution of coal tar to the efficacy of Goeckerman therapy is minimal [54]. The *Ingram regimen* is a variation of the Goeckerman regimen in which an anthralin – salicylic acid paste is applied after tar baths and UV radiation.

In addition to tar and anthralin, phototherapy (UVB) effectiveness can be enhanced when combined with other topical and systemic drug treatments. These include corticosteroids, calcipotriene, methotrexate [*59-05-2*] and retinoids.

Systemic Therapy. Use of systemic drugs is reserved for cases of severe or widespread psoriasis. These drugs fall into three main categories: cytotoxic agents, retinoids, and immunomodulators.

Cytotoxic drugs exert a suppressive effect on rapidly proliferating tissue by blocking nucleic acid synthesis. They are used primarily in cancer chemotherapy, but may be used to treat severe, recalcitrant psoriasis (→ Cancer Chemotherapy). Methotrexate [*59-05-2*], a folic acid antagonist (→ Cancer Chemotherapy, Chap. 2.1), is considered the most effective chemotherapeutic agent for psoriasis [55]. Hepatotoxicity and immunosuppression are major drawbacks to long-term therapy with methotrexate.

Hydroxyurea [*127-07-1*], 6-thioguanine [*154-42-7*] (→ Cancer Chemotherapy, Chap. 2.7), azathioprine [*446-86-6*], and mycophenolic acid [*24280-93-1*] are other antimitotics that have been used to treat psoriasis. Like methotrexate, their use is limited by severe toxicity.

Oral retinoids, including the aromatic retinoic acid derivative etretinate [*54350-48-0*] and its corresponding carboxylic acid form, acitretin [*55079-83-9*], are highly effective in selected forms of psoriasis. The pustular and exfoliative subtypes of psoriasis are more responsive to these retinoids than plaque psoriasis. Acitretin has a more favorable elimination profile from the body than etretinate, with a half-life of about 50 hours for the acid versus 120 days for the ester. Etretinate may persist for several years because of its tendency to be stored in body fat. Systemic retinoids are sometimes combined with psoralen photochemotherapy [56].

Immunomodulatory compounds directly prevent T-lymphocyte activation or prevent cytokines from acting on their target cells. Cytokines released by activated T-cells are considered the primary inducers of the accelerated keratinocyte proliferation and inflammation so characteristic to psoriasis.

Cyclosporine (cyclosporin A) [*59865-13-3*], an orally administered calcineurin inhibitor, suppresses the immune system by preventing the production of IL-2 release by T-lymphocytes [57]. Cyclosporine is highly effective for all forms of psoriasis, especially those exhibiting severe inflammation. It is commonly used to bring severe psoriasis under control, followed by a switch to other systemic or topical drugs for maintenance therapy. Long-term use of cyclosporine is limited because of its side effects of renal toxicity and hypertension.

Biologic agents, which are large protein molecules synthesized by living organisms, have been designed to specifically interfere with abnormal T-lymphocyte or cytokine functions [33]. These agents are highly effective therapeutic regimens for moderate to severe psoriasis. Because of their immunosuppressive properties, biologic treatments could potentially augment the rates of infections and cancer in susceptible patient populations.

Alefacept, a dimeric human fusion protein that binds to the CD2 lymphocyte receptor, is given by intravenous or intramuscular routes. The interaction of alefacept with CD2 causes inhibition or enhancement of T-lymphocyte binding to other immune cells. Clearing of psoriasis by alefacept is accompanied by reduced numbers of T-lymphocytes and lowered cytokine levels in lesional skin [58].

The T-lymphocyte is also the target of *efalizumab*, a humanized monoclonal antibody administered subcutaneously. Efalizumab binds to CD11a, the alpha-subunit of lymphocyte function-associated antigen-1 (LFA-1). This binding prevents LFA-1 on T-cells from interacting with intercellular adhesion molecules on endothelial cells and antigen presenting cells, thereby blunting the inflammatory process.

A key pathogenic cytokine in psoriasis is tumor necrosis factor-α (TNF-α). *Etanercept* is a subcutaneously administered dimeric fusion protein that contains the ligand-binding portion of the TNF-α receptor. By acting as a soluble TNF-α receptor, etanercept binds to free TNF-α and prevents it from interacting with the TNF-α receptors on immune and skin cells.

Photochemotherapy. Although the effects of systemic chemotherapy are nonselective, the combination of a photosensitive compound and UV radiation restricts the therapeutic action of a drug to areas of epidermal hyperplasia. An ideal photosensitizer is activated by relatively low doses of UV radiation and is otherwise inert.

Psoralens are natural furocoumarins well-known for their photosensitizing potential. Porphyrins, including hematoporphyrin derivatives (HPD), are also potent photosensitizers. Both

psoralens and porphyrins have an action spectrum in the UV-A range. Porphyrins are also activated by visible light.

Photoactivated psoralens covalently bind to DNA pyrimidines, producing monoadducts and cross-links, thereby inhibiting DNA synthesis and cell proliferation. Suppressive effects of PUVA (psoralen and UV-A) on the immune system, particularly T-lymphocytes, have been demonstrated in animals and humans. The mechanism of action of PUVA therapy in psoriasis is presumably related to its antiproliferative and immunosuppressive effects [59].

In PUVA therapy, 8-methoxypsoralen [*298-81-7*] is orally administered 2 h before exposure to increasing doses of UV-A. An average of 20 treatments over a 3-month period has been shown to be highly effective as initial therapy for psoriasis. In addition, PUVA therapy is valuable in treating other skin disorders, including vitiligo, mycosis fungoides, and atopic dermatitis.

Long-term side effects of PUVA primarily affect skin, immunologic and ocular systems. With PUVA, premature aging of skin is common but the major concern is increased risk of cutaneous malignancies. The risk of squamous cell carcinoma is definitely increased in patients treated over many years with PUVA [60]. It is also possible that the immunosuppressive effects associated with PUVA therapy can contribute to development of skin neoplasia. Eye protection during PUVA therapy is essential to prevent cataracts.

3.4. Antifungals (→ Antimycotics)

Superficial fungal infections are frequently caused by dermatophytes of the genera *Microsporum, Epidermophyton,* and *Trichophyton.* The most common dermatophyte infections are tinea cruris, tinea corporis, tinea pedis, tinea unguium, and tinea capitis. Superficial mycoses are also caused by the yeasts *Malassezia ovalis*, the etiological agent in tinea versicolor, and *Candida*.

The causative organisms are predominantly localized in keratinized areas of the skin, hair, and nails.

Topical agents are generally satisfactory for the treatment of dermatophytosis, cutaneous candidiasis, and tinea versicolor, but are often ineffective for infections of the nail and scalp. Oral agents are usually required for extensive or refractory dermatophytosis or tinea versicolor.

The following drugs are commonly employed in the treatment of superficial fungal or yeast infections. Some of these agents are also used to treat systemic mycoses.

Azoles (→ Antimycotics, Chap. 2). The broad-spectrum azoles are a large family of antifungal agents classified as belonging chemically to either imidazole or triazole classes [61], and are active against dermatophytes, yeasts, dimorphic fungi, some gram-positive bacteria, and certain protozoa. They exert their antifungal effect primarily by blocking the synthesis of ergosterol, an important regulator of cell membrane permeability [62, 63].

Topical azoles, such as clotrimazole [*23593-75-1*] and econazole [*27220-47-9*], are effective in treating cutaneous candidiasis and most tinea infections [64 – 67]. They are generally considered superior to such agents as tolnaftate, haloprogin, and undecylenic acid. No significant difference in the safety or efficacy of various azoles has been established.

Combinations of topical azoles and corticosteroids (e.g., miconazole plus hydrocortisone; clotrimazole plus betamethasone dipropionate [*5593-20-4*]) are popular for acute inflammatory mycoses. The steroid component appears to provide rapid symptomatic relief without interfering with antifungal efficacy [68]. Also, some topical azoles have been reported to exert an anti-inflammatory effect [69].

itraconazole, and fluconazole are orally active agents. Ketoconazole and itraconazole are highly effective in all superficial fungal infections. Oral ketoconazole is generally used to treat deep mycoses (e.g., paracoccidioido mycosis and histoplasmosis) or resistant superficial mycoses (e.g., chronic mucocutaneous candidiasis) and is the drug of choice in tinea versicolor. Itraconazole and fluconazole are effective in the treatment of onychomycosis, a common fungal infection of the fingernail and toenail as well as systemic infections [70, 71]. Fluconazole primarily focuses on yeasts (*Candida albicans*).

Allylamines. Terbinafine hydrochloride [*78628-80-5*] is a second generation allylamine structurally related to naftifine. Terbinafine is 10 to 100 times more potent than naftifine in vitro.

Both agents inhibit squalene oxidase and decrease ergosterol, an essential component of cell membranes in fungi. Topical terbinafine is indicated for tinea infections while oral terbinafine is indicated for the treatment of onychomycosis of the toenail or fingernail due to dermaytophytes.

Butenafine hydrochloride [*101827-46-7*] is a benzylamine, structurally related to the allylamines, and is indicated for tinea pedis. It is active against *E. floccosum, T. mentagrophytes and T. rubrum.*

Ciclopirox. Ciclopirox olamine [*41621-49-2*] (→ Antimycotics, Chap. 6), a pyridone–ethanolamine salt, is structurally dissimilar to other antifungal agents. Its primary mode of action appears to be inhibition of transmembrane transport of substrates and ions essential for cell metabolism and energy production. Ciclopirox is similar to the imidazoles in antimicrobial spectrum, therapeutic uses, and efficacy. Limited studies suggest superior penetration of topical ciclopirox into horny material and nails.

Acidic Compounds. Acidic compounds reduce the local pH to levels unfavorable for dermatophyte growth. Undecylenic acid [*112-38-9*], an 11-carbon unsaturated fatty acid, is the most widely used compound in this class; however, it is effective in only 50 % of the patients. Zinc or calcium salts of undecylenic acid are also used.

Similarly, the fungistatic activity of triacetin [*102-76-1*] (glyceryl triacetate) results from its hydrolysis by fungal esterases to acetic acid.

Tolnaftate. Tolnaftate [*2398-96-1*] is a thiocarbamate derivative similar in spectrum of action and efficacy to undecylenic acid. It is most often used in dermatophyte and tinea versicolor infections.

Haloprogin. An iodinated trichlorophenol, haloprogin [*777-11-7*] has a broad spectrum of activity against dermatophytes, *Candida* and *Pityrosporon.* It is similar to tolnaftate in efficacy for tinea cruris, tinea corporis, and tinea pedis.

Morpholine Derivatives. Amorolfine [*67467-83-8*] is a morpholine derivative which possesses both fungistatic and fungicidal activity in vitro [72]. Amorolfine is an effective antifungal agent for patients with onychomycosis and dermatomycosis caused by dermatophytes, yeasts, and sensitive molds.

Griseofulvin (→ Antimycotics, Chap. 5)**.** Griseofulvin [*126-07-8*] is a safe, effective, orally administered fungistatic antibiotic that inhibits cell mitosis by binding to microtubules during metaphase. Griseofulvin is active only against dermatophytes and concentrates in the keratinized outer layer of the stratum corneum. Absorption of griseofulvin is increased by fat intake, reduction in particle size, and multiple-dose regimens.

Griseofulvin is effective for superficial dermatophyte infections of the skin, hair, and nails and is generally reserved for infections that have failed to respond to topical therapy. It is considered the drug of choice for tinea capitis. Griseofulvin has no action against *C. albicans* or tinea versicolor.

Polyenes. Nystatin [*1400-61-9*] (→ Antimycotics, Chap. 3) is a polyene macrolide antibiotic that binds to sterol constituents in the yeast cell membrane, thereby altering its permeability. Nystatin is active against various yeast and fungi, but is most often used topically in treating cutaneous and mucocutaneous candidiasis. Nystatin is ineffective in dermatophyte infections.

Like nystatin, amphotericin B [*1397-89-3*] (→ Antimycotics, Chap. 3.1) exerts its antifungal activity by an effect on cell membrane permeability. It may also increase T-cell and B-cell responsiveness. Topical amphotericin is used primarily for cutaneous and mucocutaneous candidiasis and has been shown to be as effective as nystatin in intertriginous candidiasis.

Amphotericin is commonly administered intravenously for the management of various deep mycoses. It has been associated with significant toxicity, including impaired renal function.

Miscellaneous Topicals. Diiodohydroxyquinoline [*83-73-8*] (iodoquinol) and iodochlorhydroxyquinoline [*130-26-7*] (clioquinol) are antimicrobial agents used alone or in combination with cortisol (hydrocortisone) for treating *Candida* and dermatophyte infections, although their efficacy has not been definitely established.

Gentian violet [*548-62-9*] is a mixture of methylpararosanilines used for cutaneous or mucocutaneous candidiasis. Castellani's paint

[*8052-17-3*] contains basic fuchsin, boric acid, phenol, and resorcinol in a water–ethanol–acetone solution and is of benefit in subacute and chronic dermatophytosis. Whitfield's ointment, a 2 : 1 combination of the fungistatic agent benzoic acid [*65-85-0*] and the keratolytic salicylic acid, is helpful in the treatment of chronic dermatophytosis of the palms and soles and in tinea versicolor. Sodium thiosulfate [*10102-17-7*], selenium sulfide [*7488-56-4*], and acrisorcin [*7527-91-5*] are primarily effective in tinea versicolor. Zinc pyrithione [*13463-41-7*] is effective as an anti-*Pityrosporum* agent.

3.5. Antiaging

Skin undergoes aging by two separate and distinct processes: intrinsic aging and photoaging. Chronic sun exposure of the skin leads to photoaging, defined as photodamage superimposed on the natural (intrinsic) aging process. In contrast to intrinsically aged skin, photoaging is manifested by coarse wrinkles, reduced elasticity, darkened and uneven pigmentation and roughness. The main histologic features of intrinsic aging are epidermal and dermal atrophy while the hallmark of photoaging is dermal elastosis. Photodamage is likely mediated by destruction of extracellular matrix (collagen and elastin) of the dermis by matrix degrading metalloproteinases.

Topical tretinoin is a pharmacologic agent shown to have proven efficacy in treating photoaged skin [73, 74]. Tretinoin can enhance the appearance of photodamaged skin by effacing fine wrinkles, lightening hyperpigmented age spots, reducing roughness and improving the overall texture of the skin surface.

Botulinum toxin A, a protein produced by *Clostridium botulinum*, is indicated for the effacement of large wrinkles between the eyes (glabellar lines). The toxin, when injected subcutaneously, blocks the contractile function of subcutaneous muscles, thereby lessening their ability to furrow the skin into a creased pattern [75]. Botulinum toxin type A is taken up by nerve terminals at neuromuscular junctions and subsequently inhibits the release of acetylcholine from synaptic vesicles. Due to its endopeptidase activity, the toxin specifically cleaves and inactivates SNAP-25 protein, which is required for the fusion of synaptic vesicles with the plasma membrane [76].

1. Historical Review

The symbol used by the ancient Egyptians to represent a launderer was a pair of legs immersed in water. This choice was logical, because at that time the standard way to wash clothes was to tread on them. The "fullones" of ancient Rome earned their bread, too, by washing clothes with their feet. The washing process then was very simple: laundry of every kind was subjected to purely mechanical treatment consisting of beating, treading, rubbing, and similar procedures. It has long been known, however, that the washing power of water can be increased in various ways. Rainwater, for example, was found to be more suitable for washing than well water. Hot water also was found to have more washing power than cold, and certain additives seemed to improve any water's effectiveness.

Even the ancient Egyptians used soda ash as a wash additive. This was later supplemented with sodium silicate to make the water softer. These two substances also formed the basis for the first commercial detergent brand to appear on the German market, Henkel's "Bleichsoda", introduced in 1878. Its water-softening effect was a result of the precipitation of calcium and magnesium ions, and it simultaneously eliminated iron salts, which had a tendency to turn laundry yellow. Used along with soap, which had also been known since antiquity, this product prevented the formation of inactive material known as "lime soaps", and the laundry no longer suffered from a buildup of insoluble soap residues.

Soap is the oldest of the surfactants. It was known to the Sumerians by ca. 2500 B.C., although the Gauls were long credited with its discovery. For more than 3000 years, soap was regarded strictly as a cosmetic — in particular

a hair pomade — and as a remedy. Only in the last 1000 years has it come to be used as a general purpose washing and laundering agent. Soap remained a luxury until practical means were discovered for producing soda ash required for saponification of fats. With the beginning of the 20th century and the introduction in Germany of the first self-acting laundry detergent (Persil, 1907), soap took its place as one ingredient in multicomponent systems for the routine washing of textiles. In these, soap was combined with so-called builders, usually sodium carbonate, sodium silicate, and sodium perborate. The new detergents were capable of sparing people the weather-dependent drudgery of bleaching their clothes on the lawn, and the enhanced performance of these new agents substantially reduced the work entailed in doing laundry by hand.

The next important development was the transition brought about by technology from the highly labor-intensive manual way of doing laundry to machine washing. This change in turn led to a need for appropriate changes in the formulation of laundry detergents. Soap, notorious for its sensitivity to water hardness, was gradually replaced by so-called synthetic surfactants with their more favorable characteristics. The term "synthetic surfactants" is erroneous when used to distinguish from soap, which itself is made through synthesis as well. The first practical substitutes for soap were fatty alcohol sulfates, discovered in Germany by Bertsch and coworkers in 1928 [43]. The availability of synthetic alkyl sulfates based on natural fats and oils made possible the first neutral detergent for delicate fabrics: Fewa, introduced in Germany in 1932. This was followed in 1933 on the U.S. market by Dreft, a similarly conceived product. Fatty alcohol sulfates and their derivatives (alkyl ether sulfates, obtained by treating fatty alcohols with ethylene oxide and subsequent sulfation) still retain their importance in many applications, particularly in heavy-duty detergents, specialty detergents, dishwashing agents, cosmetics, and toiletries. The general acceptance worldwide of synthetic surfactants, with their reduced sensitivity to water hardness relative to soap, is a development of the 1940s. Procter & Gamble introduced the synthetic detergent Tide in the USA in 1946. By the 1950s the widespread availability of tetrapropylenebenzenesulfonate (TPS), a product of the petrochemical industry, had largely displaced soap as the key surfactant from the detergent market in the industrialized nations. The only remaining role of soap in the industrialized countries became that of a foam regulator. The favorable economics associated with TPS, along with its desirable properties, caused this branched-chain synthetic surfactant to capture ca. 65 % of the total synthetic surfactant demand in the Western world in the late 1950s.

However, a new criterion soon appeared for surfactants, a criterion that had long been ignored: the biodegradability of the products. As a result of several unusually dry summers in Germany, especially that of 1959, water flow in many streams and rivers was severely restricted. Great masses of stable foam began to build up in the vicinity of weirs, locks, and other constructions in waterways. These were caused by insufficiently biodegraded TPS and nonylphenol ethoxylates, another class of surfactants that had been introduced at that time. The discovery that many surfactants could emerge unchanged even from a modern sewage treatment plant and thus enter surface waters led to adoption of the first German Detergent Law in 1961 [44], whose provisions took effect in 1964 [45]. Manufacturers were subsequently enjoined from marketing any detergents or cleansing agents whose biodegradability fell below 80 % in a test devised by the Detergent Commission. Initially only anionic surfactants were affected, but these were later joined by nonionic surfactants. The German precedent was soon followed by the enactment of similar legislation in such countries as France, Italy, and Japan. In the UK and the USA, the transition to biodegradable surfactants occurred as a result of voluntary agreements between industry and government.

For a long time branched alkylbenzenesulfonates and nonylphenol ethoxylates have been replaced in most countries by the much more rapidly and effectively degradable linear alkylbenzenesulfonates and long-chain alcohol ethoxylates.

Another important step in the development of laundry detergents was replacement of builders such as sodium carbonate by complexing agents. The first complexing agents that were used were of the sodium diphosphate type, but these were replaced after World War II by the more ef-

fective sodium triphosphate. Inorganic ion exchangers such as zeolite A have meanwhile replaced sodium triphosphate in many countries, particularly in those where phosphate legislation has been enacted. Table 1 summarizes the performance characteristics of detergents containing various builders and surfactants [46].

The last decades also saw the introduction of other ingredients for improving detergency performance, and their presence in formulations has been state of the art for modern laundry detergents. Key ingredients among these are the following:

Ion exchangers (zeolites)
Soil antiredeposition agents
Enzymes
Fluorescent whitening agents
Foam regulators
Bleach activators
Soil repellents
Polycarboxylate cobuilders

Table 2 shows highlights of the historical development of detergent ingredients and detergents with concurrent developments in textile fibers and washing machines. Comparison of the changes clarifies how closely the various participants in the washing process are tied to one another. The laundry occupies the center of the stage, and it has consistently kept pace both with detergents and with available washing processes and machines, at least to the extent that the newly developed textiles have been found to have value and market appeal. Thus, close cooperation between all manufacturers involved has become essential for the development of more and more optimized washing processes.

2. Physical Chemistry of the Washing Process

2.1. Introduction to the Washing Process

Washing and cleaning in aqueous wash liquor is a complex process involving the cooperative interaction of numerous physical and chemical influences, and occurs as a result of nonspecific adsorption of surfactants on the various interfaces present [47] and through specific adsorption of chelating agents on certain polar soil components [48]. The nature of the soil as well as the water quality and the nature of the fibers to be cleaned also play a major role in the process. In the broadest sense, washing can be defined as both the removal by water or aqueous surfactant solution of poorly soluble matter and the dissolution of water-soluble impurities from textile surfaces.

The three important components of the washing process are soil, substrate, and water or washing liquid. Different kinds of soils can undergo interactions with one another, and in most cases the soils are mixed soils consisting of several different components. The detergent components are dissolved and transported through the liquid, and interactions occur with all the main components: soil, water, substrate, and detergent components. In this chapter the interactions are explained with respect to the different steps of the soil removal process (Fig. 1).

Figure 1. Different steps of the soil removal process

The fabrics are wetted by the soil and the washing liquid. Wetting by the washing liquid is enhanced by the surfactants of the detergent. The surfactants are adsorbed on the soil and on the fabric surface and, via a rolling-up process, they contribute to the removal of fatty and oily soils. Adsorption of surfactants on the surface

Table 1. Properties of detergents based on different surfactants and builders

Detergent	Single wash cycle performance	Soil antiredeposition capability	Deposition on fabrics and washing machines	Yellowing and bad odor
Soap–sodium carbonate–sodium silicate	poor	poor	very heavy	heavy
Synthetic nonionic surfactants–sodium carbonate–sodium silicate	fair to good	fair	heavy	none
Synthetic surfactants–sodium diphosphate	good	fair to good	heavy	none
Synthetic surfactants–sodium triphosphate	good	good	weak	none
Synthetic surfactants–sodium triphosphate–zeolite 4 A	good	good	weak	none
Synthetic surfactants–zeolite 4 A–polycarboxylates–sodium carbonate	good	good	weak	none

of particular soils and fabrics also plays a major role in the removal of these particles. Another important parameter in the soil removal process is the presence of ions and electrically charged molecules. The release of calcium ions from soil deposits and fibers loosens the structure of the residue. Compression by electrolytes of the electrical double layer at interfaces is also significant [47].

When removed from the surface the soil must be stabilized in the washing liquid to prevent redeposition, which in most cases leads to a graying effect of the fibers. Stabilization is obtained through emulsification and dispersion of the soils in the washing liquid. The terms secondary wash performance or multiple wash cycle are used to describe these phenomena, in contrast to the soil removal mentioned above, which is often described in terms of primary wash performance. Other physicochemical processes important for the liquid–liquid interface are the interfacial tension and viscosity, as well as the electric charge and the penetration of the active ingredient.

As a last step in the washing process one can consider adsorption of surface-active substances on the fibers. This may lead to an increased softening effect or to weaker interactions between soil and fabrics for future soiling. Hence the soil will be more easily removed during the next washing cycles. These effects are described in Sections 2.4.5 and 2.5.4.

Another way to organize the physicochemical phenomena of the washing process is related to the different interfaces in the washing system, that is, the air–water, liquid–liquid, solid–liquid, and solid–solid interfaces. Important parameters concerning the air–water surface are the surface tension of the liquid, which should be as low as possible to achieve good wetting and solubility properties. Also foam generation and film elasticity and viscosity are decisive factors. Concerning the solid–liquid interface important parameters are the disjoining pressure, suspension stability, and electric charge, whereby for solid–solid interfaces adhesion, flocculation, heterocoagulation, and sedimentation must be considered.

The interfacial chemical properties undergo changes as detergent compounds are adsorbed, and these changes are prerequisite to effective soil removal. The significance of a given change in respect to the overall process can vary, depending on the system involved. However, in general, the greater the equilibrium adsorption of washing-active substances, and the more favorable their adsorption kinetics, the better their detergency performance [47].

2.2. Components

2.2.1. Substrates

The type of fiber generally has a dramatic influence on the degree of hydrophobicity/hydrophilicity, the wettability, and the extent of soil removal. The active groups of cotton, the most common fiber material in Western Europe, are hydrophilic and have a negative surface charge when placed in water. Because of the negative surface charge, cotton has specific characteristics and can interact with soil in a different way than other synthetic fibers. Cotton also has a large amount of calcium at its surface, which makes it difficult to remove the soil. This is a characteristic difference to synthetic fibers. Through different kinds of surface treatment nature and characteristics of the fiber surface can be changed and hence soil removal improved.

The different effects that complexing agents and surfactants have on a series of fibers are clearly demonstrated in terms of soil removal in

Table 2. Development of washing equipment from 1876 to 2000

Year	Detergent ingredients	Detergents	Textile fibers	Washing equipment
1876	sodium silicate soap starch		cotton linen wool	boiler
1878	sodium carbonate sodium silicate	prewashing product and laundry softener (Henko, Henkel, Germany)		
1890			cupro	
1907	soap sodium carbonate sodium perborate sodium silicate	heavy-duty detergent (Persil, Henkel, Germany)	rayon acetate silk	wooden vat machine
1913	proteases (pancreatic enzymes)	prewashing product (Burnus, Röhm & Haas, Germany)		
1920			viscose staple fiber	metal tub agitator washing machine
1932/33	synthetic surfactants (fatty alcohol sulfates)	specialty detergent (Fewa, Henkel, Germany; Dreft, P & G, USA)		
1933	sodium diphosphate magnesium silicate	heavy-duty detergent (Persil, Henkel, Germany)		
1940	alkylsulfonates (Mersolat) antiredeposition agents (CMC[a])	heavy-duty detergent (Henkel, Unilever, Germany)		automatic agitator washing machine (Blackstone, USA)
1946	fatty alcohol sulfates alkylbenzenesulfonates sodium triphosphate	heavy-duty detergent (Tide, P & G, USA)	polyamide	automatic drum-type machine (Bendix, USA)
1948	nonionic surfactants	heavy-duty detergent (All, Monsanto, USA)		
1949	fluorescent whitening agents (optical brighteners)	rinsing additive (Sil, Henkel, Germany)		
1950	fragrances cationic surfactants	heavy-duty detergent (Dial, Armour Dial, USA) fabric softener (CPC International, USA)		
1954	anionic–nonionic combinations foam-regulators (soap)	 heavy-duty detergent (Dash, P & G, USA)	polyacrylonitrile	semiautomatic drum-type machine (washing automatically, rinsing by hand, spinning separately, Europe)
1957			polyester resin-finished cotton	automatic drum-type machine (washing and rinsing automatically, spinning separately, Europe)
1959	proteases (enzymes)	prewashing detergent (Bio 40, Gebr. Schnyder, Switzerland)		
1962	foam-regulators (behenate soap)	heavy-duty detergent (Dash, P & G, Germany)	polyester–cotton blend	fully automatic drum-type machine (washing, rinsing, and spinning automatically, Europe)
1965			polyurethane wool with reduced felting	wash dryer (washing, rinsing, spinning, and tumble drying automatically in one machine)
1966			nonwovens	
1970	fatty acid amine condensation product	detergent for delicates with fabric softening effect (Perwoll, Henkel, Germany)	resin-finished linen	
1972	bleach activators (TAGU) [b] NTA [c]	heavy-duty detergent (Cid, Henkel, Germany) heavy-duty detergent (various brands, Canada)		

Table 2. Continued

1973	amylases (enzymes)	heavy-duty detergent (Mustang, Henkel, Germany)		
1974	sodium percarbonate	heavy-duty detergent (Dixan, Henkel, Cyprus; Persil, Lever, UK)		
1975	sodium citrate	heavy-duty liquid detergent (Wisk, Lever, USA)		
1976	zeolite 4 A	heavy-duty detergent (prodixan, Henkel, Germany; Tide, P & G, USA)		
	foam-regulators (silicone oils)	heavy-duty detergent (Mustang, Henkel, Germany) heavy-duty liquid detergent without builders (Era, P & G, USA)		
1977	layered silicates–cationic surfactants	dual-function detergent with fabric-softening effect (Bold 3, P & G, USA)		
1978	bleach activator	heavy-duty detergent	Dunova (modified polyacrylonitrile fiber)	microprocessor operation, electronic sensing
	TAED[d]	(Skip, Lever, France)		
1981		liquid heavy-duty detergent in Europe (Liz, Henkel, Germany; Vizir, P & G, Germany		
	esterquats	fabric softeners (Minidou, Lesieur Cotelle, France)		
1982	zeolite 4 A–NTA builder systems	nonphosphate heavy-duty powder detergent, (Dixan, Henkel, Switzerland)	PTFE[e]-fiber Goretex	
1984	poly(acrylic acid), poly(acrylic acid-*co*-maleic acid)	heavy-duty detergents		
1986			PES[f]-polyether fiber Sympatex	controlled water intake (Europe)
1987		compact heavy-duty detergent (Attack, Kao, Japan)		
	cellulase (enzyme)	compact heavy-duty detergent (Attack, Kao, Japan)		
	soil repellent	heavy-duty detergents, USA		
1988	lipase (enzyme)	compact heavy-duty detergent (Hi Top, Lion, Japan)		
1990	alkylpolyglycosides (APG)	liquid heavy-duty detergent (Persil, Henkel, Germany)		
	foam regulators (paraffins)	heavy-duty detergent (Persil, Henkel, Germany)		
1991	dye transfer inhibitor PVP[g]	heavy-duty color detergent (Persil Color, Henkel, Germany)		
1992		extruded supercompact heavy-duty detergent (Persil Megaperls, Henkel, The Netherlands, Belgium, Austria)		
1994	*N*-methylglucamide	heavy-duty detergents (Ariel, P & G, Germany; Tide, P & G, USA)		
	bleach catalyst Mn-TACN[h]	heavy-duty detergent (Omo Power, Lever, The Netherlands; Persil Power, Lever, UK)		
1995				fuzzy logic control
1996		gel-structured liquid heavy-duty detergents (Persil Gel and Dixan Gel, Henkel, Europe)		
1997–1998		heavy-duty detergent tablets (Europe: Colon, Benckiser, Spain; Persil, Lever, UK; Le Chat, Henkel, France; Dixan, Henkel, Italy; Persil, Henkel, Germany)		

[a] CMC = carboxymethyl cellulose.
[b] TAGU = tetraacetylglycoluril.
[c] NTA = nitrilotriacetic acid.
[d] TAED = tetraacetylethylenediamine
[e] PTFE = polytetrafluoroethylene
[f] PES = poly(ethylene glycol terephthalate)
[g] PVP = poly(*N*-vinylpyrrolidone)
[h] Mn–TACN = manganese–tetraazacylononane complex

Figure 2. The anionic surfactant selected in this case (alkylbenzenesulfonate) has virtually no effect on cotton, whereas even by itself sodium triphosphate, as an example of a complexing agent, brings about substantially improved soil removal. Permanent press cotton also shows a greater effect for sodium triphosphate than for surfactants alone. The effect of sodium triphosphate is particularly pronounced with the relatively hydrophilic synthetic fibers polyamide and polyacrylonitrile. This behavior changes when more hydrophobic textile fibers are used. An effect is still apparent with polyester/cotton and polyester, but it is not greater than that of surfactants alone. At the same time, overall wash performance decreases. In the case of the very hydrophobic polyolefin fibers, the wash effectiveness of the surfactant is substantially greater than that of the complexing agent. These examples show the synergistic way in which surfactants and complexing agents or ion exchangers complement each other, not only in the case of mixed soils, but also with regard to removing soil from different fibers.

Figure 2. Influence of textile fibers on soil removal *S* [46] Detergents: a) 1 g/L Alkylbenzenesulfonate + 2 g/L sodium sulfate; b) 2 g/L sodium triphosphate; c) 1 g/L alkylbenzenesulfonate + 2 g/L sodium triphosphate

2.2.2. Washing Liquid/Water

The most obvious role of water is to serve as a solvent, both for the detergent and for soluble salts within the soil. Water is also the transport medium for dispersed and colloidal soil components, however. The washing process begins with wetting and penetration of the soiled laundry by the detergent solution.

The degree of hardness is one of the most important parameters of the water itself. Water hardness is defined in terms of amount of calcium and magnesium salts solved in the water. In different regions and countries the water hardness can vary. In most European regions the water is hard. In North America, Brazil, and Japan, the water is comparatively soft. The ions in the washing water can have different effects on the washing process. For example ion exchange with the counterions of the soaps and surfactants of the detergent can take place, and insoluble calcium or magnesium compounds are formed instead of soluble sodium compounds. This binds the surfactant and hinders it in contributing to the soil removal process. The precipitates thus formed may also have an impact on the washing machine and the fabrics to be washed, because they form residues which are difficult to remove. Moreover, high calcium content in the washing water may have an influence on the removal of particulate soil.

The presence of trace amounts of iron, copper, or manganese ions in water may also be detrimental to washing. These ions can catalyze decomposition of bleaching agents during the washing process. Complexing agents or ion exchangers are often found in detergents, and one of their functions is to bind multivalent alkaline earth and heavy-metal ions through chelation or ion exchange.

Table 3. Surface tension of different solvents

Solvent	Surface tension, mN/m
Water	72.5
Hexane	19.5
Decane	23.9
Benzene	28.4
Toluene	29.3
Chlorobenzene	33.2
Tetrachloromethane	25.7
Cyclohexane	24,7

One of the important functions of water, besides being a transport medium for the active substances of the detergent and for the soil after removal, is to wet and penetrate into the fabrics. Water has a very high surface tension (72 mN/m). To obtain a more effective wetting behavior the surface tension of water must be reduced to the usual surface tension level of organic solvents. As a comparison the surface tensions for water and some organic solvents is shown in Table 3 [49]. The reduction of sur-

face tension can be achieved through the surface-active properties of the surfactants, which effectively reduce the surface tension of water to values of 30 mN/m and below. The surfactants thus become key components of any detergent. This will be further explained in Section 2.4.2.

Other important parameters which may influence the washing process are mechanical input, washing time, and temperature.

2.2.3. Soils

One way to categorize soils is by their origin, i.e., residues from domestic activities like cooking or gardening, impurities from industrial or commercial activities, bodily excretions, and dust from the atmosphere.

From a detergency standpoint, however, it is more appropriate to regard the principal types of soil in terms of their chemical properties, for example, water-soluble materials such as sugar, inorganic salts, urea, and perspiration, and solid particles such as rust/metal oxides, soot (carbon black), carbonates, silicates, humus etc. Another big group of substances are fats and oils such as animal fat, vegetable fat and oil, sebum, mineral oil, and grease. These are very common soils resulting from domestic and industrial activities and can in principle be removed with surfactants, which are one of the main components of detergents. Proteins such as blood, grass, egg, milk, and keratin from skin are another group of soils. These require enzymes to cleave them into smaller parts before they can be removed by the surfactants. Another group of stains can only be removed by chemical reactions. These are typically wine, coffee, tea, fruit juices, and vegetable stains.

Often, these stains are not in pure form. Most stains are mixtures of two or more components, for example, a pigment and a fat or oil. Moreover, interactions between the soils can make them even more difficult to remove. Hence, removing these soils is the combined work of several detergent components.

The removal of common stains like solid particles and fat or oil takes place in pure interfacial processes through the action of surfactants, that is, without any chemical change of the soils, whereas other types of stains can only be removed by chemical changes of the colored molecules. One example of the latter is the removal of bleachable stains, like the above-mentioned wine, tea, and coffee, which in most cases is an oxidation reaction leading to changes in the properties of the colored substance that turn it into a colorless substance. In some cases the colorless residue stays on the fabric, and sometimes the chemical change may result in easier removal from the fabric. The same is true for proteins. Through the action of enzymes they go through a chemical change and are cleaved into smaller molecules which can then be removed more easily. Among the most difficult soils to remove from fabrics are pigments, such as carbon black, inorganic oxides, carbonates, and silicates. Other problematic soils include fats, waxes, higher hydrocarbons, denatured protein, and certain natural dyes. Mostly these stains are present on the fibers in the form of mixed soils.

Apart from surfactants, enzymes, and bleach, other components taking part in the soil removal process are water-soluble complexing agents and water-insoluble ion exchangers. In the following chapters, the physicochemical effects of these different soil removal processes will be explained.

2.3. Wetting/Adsorption on Surfaces

2.3.1. Wetting

In the first phase of washing, textile fibers and soil must be wetted as thoroughly as possible by the wash liquor [50]. Wetting is a complex process which is determined by the interaction of the different interfacial tensions between the solid surface, the liquid and the gas phase. A contact angle θ between the solid and a drop of a liquid applied to its surface is formed and this can be taken as a measure of wetting (Fig. 3). The contact angle depends on the structure of the surface and the surface tension of the liquid.

To a first approximation, wetting can be described by the Young equation [47, 51]:

$$\gamma_S = \gamma_{SL} + \gamma_L \cos\theta \quad (1)$$

γ_S = interfacial tension substrate/air (mN/m)
γ_{SL} = interfacial tension substrate/liquid (mN/m)

γ_L = interfacial tension liquid/air (mN/m)
θ = contact angle of the wetting liquid

Figure 3. Schematic representation of wetting of a solid surface

As the interfacial tension liquid–air and the contact angle are easily accessible by experiments, sometimes the so-called wetting tension is defined:

$$j = \gamma_S - \gamma_{SL} = \gamma_L \cos\theta \quad (2)$$

Total wetting of a solid is possible only if the liquid drop spreads spontaneously over the solid surface, e.g., when $\theta = 0$ and $\cos\theta = 1$. Strictly speaking, the limiting case described above, that of total wetting (Eq. 2), is only applicable if γ_{SL} is so reduced through adsorption that it approaches zero. With a given solid surface possessing a low surface energy, for various liquids a linear relationship normally exists between $\cos\theta$ and surface tension. The limiting value for $\cos\theta = 1$ is a constant of the solid and is referred to as its critical surface tension γ_c. This means that only those liquids with surface tension equal to or less than the critical surface tension of a given solid spread spontaneously, thus causing thorough wetting. Table 4 collects critical surface tension data for various synthetic materials.

Table 4. Critical surface tensions of several typical plastics [52]

Polymer	γ_c at 20 °C, mN/m
Polytetrafluoroethylene	18
Polytrifluoroethylene	22
Poly(vinyl fluoride)	28
Polyethylene	31
Polystyrene	33
Poly(vinyl alcohol)	37
Poly(vinyl chloride)	39
Poly(ethylene terephthalate)	43
Poly(hexamethylene adipamide)	46

Polyamide, for example, which has a γ_c of ca. 46 mN/m, is relatively easy to wet with standard commercial surfactants, whereas polytetrafluoroethylene, which has a γ_c of about 18 mN/m, is wettable only with special fluoro surfactants. This relationship simplifies the choice of a proper surfactant for a given wetting problem. More recently, special attention has been given to ultrahydrophobic surfaces, which in addition to a very high contact angle have surface structures which diminish further the contact area between liquid and solid surface. Surfaces with such properties are known to have self-cleaning properties, although applications for washing are not known until now.

To better understand and predict the mechanism of droplet spreading on surfaces, new modeling methods have been developed. The spreading of an aqueous drop on a hydrophobic surface and the adsorption of surfactants from the drop on the air–water and water–hydrophobic solid interfaces was studied by using molecular dynamics. An example of a simulated time sequence for a drop with a linear, flexible-chain surfactant is shown in Figure 4.

Figure 4. Time sequence of a drop (solvent not shown) with a linear, flexible-chain surfactant adsorbed on the interfaces of the spreading drop [53]

2.3.2. Drainage

Drainage is closely connected with wetting phenomena. Drainage is of specific importance in the rinsing step, especially for hard surfaces. The washing or cleaning liquid should completely wet the surface and rinse off in a uniform and thin film. Only few studies are related to the physicochemical effects of drainage from solid surfaces in presence of surfactants [54]. Figure 5 shows a set of drainage curves for surfactant solutions, obtained with a gravimetric method.

Figure 5. Weight of liquid film draining from a cylinder as a function of $1/(t_w + t_d)^{0.5}$ for different concentrations of a nonionic surfactant $C_{12}E_6$ and an anionic surfactant $C_{12}SO_3Na$ [54]

The drainage curve of a pure liquid is known be a linear function of $1/(t_w + t_d)^{0.5}$. With addition of surfactant the amounts of liquid remaining on the surface increase, reach a maximum, and then decrease, so that at high concentrations the drainage behavior of a pure liquid is reached again. The Gibbs–Marangoni effect, which retards the liquid flow in the interface, is the reason for this behavior. At high concentration this effect is compensated by diffusion of the surfactants. Therefore, it is important to have a high enough surfactant concentration to guarantee both complete wetting and small liquid amounts during drainage.

2.3.3. Adsorption Layer

The adsorption of components, especially surface-active substances, at interfaces in the washing process is an important mechanism which was already shown for wetting and drainage. This regards the gas–liquid, liquid–liquid, and liquid–solid interfaces. The adsorption at the gas–liquid interface Γ is related to the surface tension γ by the Gibbs equation 3

$$\Gamma = -\frac{1}{RT}\frac{\mathrm{d}\gamma}{\mathrm{d}\ln c} \tag{3}$$

Therefore surface tension–concentration curves are a useful tool to characterize this interface. Figure 6 shows the surface tension as a function of concentration for surfactants with the same alkyl chain length and different hydrophilic groups. All curves have a breakpoint which is characteristic for the critical micelle concentration (CMC) of surfactants, with the nonionic surfactant having the lowest CMC and surface tension above the CMC, whereas anionic and cationic surfactants are quite similar.

Figure 6. Surface tension as a function of concentration for different surfactants [55]

Figure 7. Influence of counterions on the surface activity of a typical anionic surfactant as a function of surfactant concentration [55]

The surface tension is dependent on alkyl chain length and electrolyte concentration (Figs. 7 and 8). Electrolytes strongly decrease the CMC of the surfactants. The same effect is observed for increasing chain length of the surfactant.

Figure 8. Surface tension of alkyl monoglycosides and alkyl polyglycosides (AGP®) [56]

The kinetics of adsorption of surfactants at the liquid–gas interface is an important aspect for applications like detergency, as in many processes the state of equilibrium is not reached. Figure 9 shows the dynamic surface tension of an anionic and a nonionic surfactant as a function of time for different concentrations. The two surfactants strongly differ. Whereas the nonionic surfactant shows strong time dependence even for high concentrations, the surface tension of the anionic surfactant only slightly changes above the CMC.

The adsorption effects at the liquid/liquid interface which are important for the removal of oily soils are quite similar to adsorption at the gas–liquid interface [58]. Table 5 lists interfacial tensions of pure oils in water [59]. The interfacial tension decreases with increasing surfactant concentration until a breakpoint is reached. This breakpoint corresponds to the CMC for the nonpolar alkane, whereas it is shifted to higher concentrations for the more polar oils. This is due to the higher solubility of the surfactant in these oils.

Table 5. Interfacial tension between water and organic solvents

System	Interfacial tension, mN/m
Water/decane	48.7
Water/isopropyl myristate	27.9
Water/2-octyldodecanol	24.2

Figure 9. Dynamic surface tension of $C_{12}SO_3Na$ (top) and $C_{12}E_6$ (bottom) as a function of concentration at 40°C [57]

Figure 10 shows the interfacial tension of different surfactants for three oils as a function of concentration. The adsorption of surfactants and ions both on the fiber and soil surface is a prerequisite for the removal of pigment soil from solid surfaces. Figure 11 shows the adsorption of a nonionic and an anionic surfactant on a typical hydrophobic pigment. In contrast to anionic and cationic surfactants, nonionic surfactants have no or little effect on surface charge [60]. Therefore, their mode of action cannot be ascribed to changes in electrical charge on pigments and fibers. Instead, the effect is related exclusively to properties of the adsorption layer. Compared to anionic surfactants, the adsorption of nonionic surfactants is quite strong at hydrophobic, weakly polar interfaces. This is illustrated in Figure 11 by the relative adsorption of dode-

cyl dodecaglycol ether and *n*-dodecyl sulfate on activated carbon black [61].

Figure 10. Effect of alkylglycoside surfactants C_nG_1 on the oil/water interfacial tension σ for three different oils: ● n-decane; ○ isopropyl myristate; ■ 2-octyldodecanol as a function of concentration c_1 at 60 °C. a) C_8G_1; b) $C_{12}G_1$ [59]

Figure 12 shows the adsorption of nonionic surfactants of the glycoside type on a hydrophilic substrate as a function of the concentration relative to the CMC [58]. The adsorbed amounts are smaller than on a hydrophobic surface by a factor of about 100. Surface coverage of a close-packed monolayer is not reached in the studied concentration range, which indicates the adsorption of isolated individual molecules.

For the soil removal of pigments and the repulsion between removed soil and the surface of the substrate the adsorption on fibers has a strong influence. As an example for this effect the adsorption of nonionic surfactants on polyester fibers is shown in Figure 13 [62]. The adsorbed amounts reach a plateau value at about the CMC and are lower for the nonionic surfactant with the longer hydrophilic group at low surfactant concentration. Considering the adsorption effects on the soils and different fibers it is important to choose the right surfactant structure for optimum adsorption effects and therefore optimum soil removal.

Figure 11. Adsorption isotherms for surfactants on activated carbon black [61]
25 °C, surface area 1150 m^2/g (from BET measurements)

1) $C_{12}H_{25}O\,(CH_2CH_2O)_{12}H$;
2) $C_{12}H_{25}OSO_3Na$

Figure 12. Adsorbed amounts m_{ads} of C_nG_1 on hydrophilic glass CPG-10 as a function of concentration relative to the CMC [58]

The adsorption of inorganic ions on fibers and soil is an effect which is often underestimated in soil removal. These ions can come from the soil, from the water (hardness ions), or from the detergent. The adsorption of inorganic ions can modify the surface charge of the solids and compete

with or enhance the adsorption of surfactants. An example of the adsorption of inorganic ions is given in Figure 14 [63]. The adsorption isotherm of Ca^{2+} ions on SiO_2 shows strong adsorption with an increase up to high concentrations. By this adsorption the negative surface charge of SiO_2 can be decreased and even reversed, so that anionic surfactants can be adsorbed on this surface [63].

Figure 13. Surface excess Γ of $C_{12}E_6$ and $C_{12}E_8$ on polyester fibers as a function of the equilibrium concentration at 25 °C [62]

Figure 14. Adsorbed amounts $\Gamma/10^{-8}$ mol g^{-1} of Ca^{2+} (▲) and Fe^{3+} (■) ions on SiO_2 as a function of log (c/mol L^{-1}) [63]

2.4. Soil Removal and Stabilization

2.4.1. Builders

2.4.1.1. Overview on Builder Systems

Besides surfactants builders play an important role in the washing process [61]. They have mainly two important functions: supporting soil removal and water softening by removing the calcium and magnesium ions resulting from water and soil. Salts of multivalent cations are almost always present in soils and on textile fiber surfaces. Examples are calcium carbonate, calcium phosphate, and calcium stearate. Cationic bridges, which are responsible for binding soil components chemically to fibers, also frequently form. This type of linkage can be due to the carboxyl groups, for example, commonly found in cotton as a result of oxidation, but such a linkage may also arise from the presence of reactive centers associated with metal oxides or from soaps derived from sebum. Problems stem principally from poorly soluble calcium salts, whose solubility is further diminished as the water hardness of the wash liquor increases. On the other hand, their solubility in distilled water is higher because of displacement of the solubility equilibrium. When calcium salts are dissolved from a multilayered soil deposit, cavities remain in the structure. These cavities loosen the deposit and facilitate its removal from the surface. Thus, one task of detergent components is to create the highest possible calcium ion concentration gradient between soil and aqueous phase during the washing process.

The substances used as builders can be very different: precipitating alkaline materials such as sodium carbonate, sodium silicate, or soaps; complexing agents like sodium triphosphate or nitrilotriacetic acid (NTA); ion exchangers such as zeolites; and polycarboxylic acids.

The choice of builder strongly depends on the type of detergent, washing conditions, and the region where the detergents are used. The physical chemistry of the builder substances is quite different and will be briefly summarized in the following.

2.4.1.2. Precipitation Builders

The performance of precipitation builders is mainly determined by the solubility product of their calcium and magnesium salts and a low affinity of these salts to the fiber. The latter effect is especially important, as the insoluble salts should not adhere to the fiber to cause residues on the surface. This is mainly influenced by additives (see Section 2.4.1.5). Sodium carbonate is the most often used precipitation builder. Calcium carbonate has a very low solubility and

therefore removes Ca^{2+} ions to low residual concentrations. Fatty acids are another possibility for the removal of calcium ions, as these substances strongly react with Ca^{2+} ions in the alkaline pH range. The solubility product is shown in Table 6 for fatty acids of different chain lengths [64]. The solubility of calcium salts of long-chain fatty acids is very low.

Table 6. Solubility products of calcium carboxylates at 23 °C [64]

Carbon no.	Solubility product
8	2.7×10^{-7}
9	8.0×10^{-9}
10	3.8×10^{-10}
11	2.2×10^{-11}
12	8.0×10^{-13}
14	1.0×10^{-15}
16	1.6×10^{-16}
18	4.0×10^{-18}

Anion concentration: 2.5×10^{-3} mol/L

2.4.1.3. Complexing Agents

Whereas surfactants are adsorbed nonspecifically at all hydrophobic surfaces, complexing agents can undergo specific attraction to surfaces that have distinct localized charges. The main process is chemisorption and is especially characteristic of metal oxides and certain fibers [48]. As shown in Figure 15, the adsorption of a complexing agent produces an effect similar to that of an anionic surfactant. The change in ζ potential for hematite is taken as illustrative.

The adsorption of the complexing agents has a significant impact on the dispersion properties. This can be shown for the sedimentation of graphitized carbon black and kaolinite in solutions of sodium triphosphate (Fig. 16) [61], but can also be observed for polar pigments such as metal oxides [65]. Whereas the settling volume V_S of graphitized carbon black hardly changes with increasing concentration of the complexing agent, kaolinite is dispersed much better at high concentration of the complexing agent, as is indicated by the lower settling volume.

Figure 16. Settling volume of graphitized carbon black and kaolinite in sodium triphosphate solutions at 16°dH water hardness, 0.30 g/10 mL graphitized carbon black, 0.50 g/10 mL kaolinite [61]

The specificity of adsorption of complexing agents with respect to metal oxides is so great that even displacement of anionic surfactants from surfaces with lower adsorption energies is possible [48].

Complexing agents suppress the adsorption of anionic surfactants on metal oxides. However, adsorption is enhanced on materials such as carbon black or synthetic fibers. This effect is due to the electrolyte character of the complexing agent. The washing process generally involves removing mixed soils that consist of both hydrophilic and hydrophobic matter from fiber surfaces. For this reason, the different specificities of complexing agents and surfactants give complementary functions to these two types of material.

Figure 17 illustrates how surfactants, salts, and complexing agents complement each other in the removal of soil. The negative influence of calcium is eliminated by sodium triphosphate or

other complexing agents. The magnitude of the indirect counterion effect of sodium ions is made clear when sodium sulfate is added to alkylbenzenesulfonate (curve b).

Figure 17. Soil removal *S* from wool as a function of water hardness at 30 °C [48]
a) Sodium alkylbenzenesulfonate (0.5 g/L); b) Sodium alkylbenzenesulfonate (0.5 g/L) together with sodium sulfate (1.5 g/L); c) Sodium alkylbenzenesulfonate (0.5 g/L) together with sodium triphosphate (1.5 g/L)

Before slightly soluble cations can be dissolved from soil and fibers, adsorption of the complexing agent takes place on the surface, particularly in those areas that contain multivalent cations. In the course of subsequent desorption of water-soluble multivalent cation complexes, many of the soil–fiber bonds are broken, leading to a marked enhancement of the washing effect. Removal of cations from soil and fibers by adsorption–desorption processes and displacement of solubility equilibria are the most important phenomena that accompany the use of complexing agents and ion exchangers in the washing process.

2.4.1.4. Ion Exchangers

Zeolites (→ Zeolites) are used to replace phosphate in many detergents to prevent eutrophication of stagnant and slowly flowing surface waters. The main type of zeolite used in detergents is zeolite A. These water-insoluble, finely dispersed ion exchangers differ in their properties from water-soluble complexing agents.

The main properties of zeolites in the washing process besides ion exchange of the calcium and magnesium ions of the water hardness are:

- Adsorption of water-soluble substances such as dyes on the zeolite particles
- Heterocoagulation of pigments and solid fats with zeolite
- Action as crystallization nuclei for sparingly soluble salts

The most characteristic feature of zeolites is the ion exchange of the sodium ions in the crystal structure by calcium and magnesium ions. Figure 18 shows the ion-exchange kinetics of zeolites A and X for calcium and magnesium ions [66]. Calcium ions diffuse at a high rate into both types of zeolite with a slight preference for the wider pore zeolite X. These differences are only evident for short times which are of not practical importance for the washing process. The ion-exchange kinetics are more strongly dependent on the pore size of the ion exchanger for magnesium ions. Despite the smaller ion radius at 25 °C the magnesium ion has a more stable and larger hydration shell than the calcium ion and therefore more slowly penetrates into the pore system of the zeolite.

Figure 18. Kinetics of ion exchange of calcium and magnesium ions for zeolite A and zeolite X (25 °C, ion concentration 5.36×10^{-3} mol/L, zeolite concentration 1 g/L) [66]

A comparison between the decrease of water hardness by ion exchange and washing performance is given in Figure 19 [67]. A decrease in water hardness from 16°dH down to 3–4°dH only slightly influences the detergency. Only a further decrease of the calcium ion concentration leads to a significant increase of soil removal from the fabric. Because zeolite A is an ion

exchanger, calcium ion exchange is decreased by a high concentration of sodium ions despite the high selectivity of the ion-exchange process. Thus detergency in the presence of sodium ions slightly decreases.

Figure 19. Influence of NaCl on the water-softening effect and the washing performance of zeolite A. Water-softening effect at 90 °C after 15 min and washing performance at 90 °C and 285 ppm water hardness on cotton soiled with particulate sebum [67]

The ion exchange of the zeolite can be described by Equation 4.

$$Q_{Ca^{2+}} = \frac{Q_m c_{Ca^{2+}}}{c_{Ca^{2+}} + 2\frac{b_2}{b_1}\left(c'_{Na^+} + 2\,Q_{Ca^{2+}}\right)} \quad (4)$$

$Q_{Ca^{2+}}$ = exchanged amount of calcium ions
Q_m = maximum exchanged amount of calcium ions
$c_{Ca^{2+}}$ = equilibrium concentration of calcium ions
c'_{Na^+} = initial concentration of sodium ions
b_1 and b_2 = constants

Zeolites show significant adsorption properties in the washing process and under the conditions of the wastewater [68]. Figure 20 demonstrates the adsorption of a cationic dye (methylene blue) and an anionic dye (benzopurpurin) onto zeolite A [66]. The cationic dye is strongly adsorbed on the negatively charged surface of zeolite A, whereas the anionic dye is only adsorbed on zeolite A which was extracted from a detergent formulation produced on a technical scale. This is due to hydrophobization of the zeolite surface in the production process, which increases the interaction of the dye and the zeolite surface.

Figure 20. Adsorption of dyes on zeolite A at 23 °C [66]

The concentration of complexing agent and the temperature are generally the decisive factors in removing multivalent metal ions by a water-soluble complexing agent; the binding ability diminishes with increasing temperature. Essentially the same relationships also apply when using a water-insoluble ion exchanger, although the temperature effect is usually reversed [69] (Tab. 7).

Table 7. Binding capacity for calcium and magnesium ions of zeolites P and A [69]

	Zeolite P	Zeolite A
Ca binding capacity at 25 °C	140–165 mg CaO/g	160–175 mg CaO/g
Ca binding capacity at 60 °C	180 mg CaO/g	180 mg CaO/g
Mg binding capacity at 25 °C	20–40 mg MgO/g	20–40 mg MgO/g

2.4.1.5. Cobuilders

The mechanisms of action for complexing agents and water-insoluble ion exchangers are different. The two complement each other in their respective roles. Figure 21 shows the way in which a small amount of a water-soluble complexing agent can increase the washing effectiveness of the water-insoluble ion exchanger zeolite A. The effect results from an increase in the rate of dissolution of divalent ions from soil and fibers. The mode of action is depicted schematically in Figure 22. The water-soluble complexing agent serves as a carrier that transports calcium from the precipitate into the water-insoluble ion exchanger. The process is based on successive adsorption, desorption, and dissociation, and it accelerates the delivery of free calcium ions into solution.

Figure 21. Comparison of soil removal S of zeolite A (a), sodium triphosphate (b), and a mixture of the two builders in the ratio zeolite A: sodium triphosphate = 9 : 1 (c); results obtained for non-resin-finished cotton tested in a Launderometer [70]
Wash time: 30 min with heating; temperature: 90 °C; water hardness: 16 °d (285 ppm)

Figure 22. Mechanistic scheme for the carrier effect [71]

Polycarboxylates are widely used in detergents as cobuilders [72 – 75]. They are able to retard precipitation of sparingly soluble calcium salts such as calcium carbonate and calcium phosphate (*threshold effect*) when used in small concentrations. As anionic polyelectrolytes they bind cations (counterion condensation), whereby multivalent cations are strongly preferred. Polycarboxylates can also disperse solids in aqueous solution. Both dispersion and threshold effect result from adsorption of the polymer on the surface of soil and $CaCO_3$ particles, respectively. Stabilization of sparingly soluble salts such as $CaCO_3$ in a colloidal state by polycarboxylates occurs at substoichiometric concentrations of the cobuilder in the washing liquor, which is an advantage compared to ion exchange or complexation. Thus, small amounts of threshold-active compounds can be used as cobuilders even in laundry detergents with a high content of sodium carbonate. The effect, however, is strongly dependent on the washing conditions, such as temperature, soda ash, and cobuilder concentration. Figure 23 illustrates the range of effectiveness (grey areas) of a polycarboxylate (AC) in a carbonate-containing system for typical European conditions of water hardness (3.04×10^{-3} mol/L Ca^{2+}) [76]. The appearance of $CaCO_3$ particles larger than ca. 0.2 μm within 30 min was taken as an indicator of the threshold effect. The results show that polycarboxylates are no longer threshold-active above 40 °C. This holds even more for higher carbonate concentrations, i.e., with detergents containing soda ash as the sole builder.

Figure 23. Precipitation inhibition of $CaCO_3$ by AC (threshold effect) as a function of temperature and soda ash concentration (3.04×10^{-3} mol/L Ca^{2+})
a) 105 mg/L AC; b) 210 mg/L AC

2.4.1.6. Soluble Builders

Different types of silicates are described as alternatives for zeolites as builders in detergents [69]. The common property of these silicates is their

solubility. They are either crystalline layered silicates, for example, δ-sodium silicate, or certain amorphous silicates. The sodium ions of these silicates are accessible and can be exchanged for calcium ions. This is shown in the isotherms of Figure 24 for δ-sodium silicate [77].

Figure 24. Equilibrium isotherms of the Na^+/Ca^{2+} system at 293 (■), 313 (●) and 333 K (▲) and total ion concentration of 0.02 N [77]

The calcium binding capacity is temperature-dependent and increases at higher temperatures. Table 8 shows the calcium- and magnesium-binding capacity for a crystalline layered silicate and an amorphous type. The calcium-binding capacity for both types is in the same range. It is interesting that the magnesium binding capacity for the two silicates is much higher than that of zeolite A. In addition, the binding capacity increases with increasing pH. The solubility of the amorphous type is higher than that of crystalline layered silicate. These silicates differ from conventional sodium silicates in their solubility, which is much lower than that of conventional silicates. Therefore the calcium ions of the washing liquor react with nonmolecularly dissolved sodium silicate to form insoluble calcium and magnesium silicates. These solids are well dispersed as fine particles and do not precipitate onto fabrics.

Table 8. Binding capacity of sodium silicates [69]

Sodium silicate	Ca binding capacity (mg CaO/g)	Mg binding capacity (mg MgO/g)
crystalline	90–110 (25°C)	100–125 (25°C)
amorphous	120–140 (40°C)	150–170 (40°C)

2.4.2. Oily Soil

In typical washing and cleansing operations the wetting situation as described in Section 2.3.1 is much more complicated, since the solid surfaces that are present tend to be irregularly covered with oily or greasy soils. Thus, the wash liquor must compete with soil in wetting the surface. Figure 25 illustrates the problem schematically.

Figure 25. Two liquids on a solid surface
a) Separated; b) Overlapping
A) Wash liquor; B) Oily dirt

If two drops of different liquids (e.g., wash liquor A and an oily residue B) are placed next to each other on a solid surface S, two different wetting tensions j_A and j_B act on the surface. If the two liquids come into direct contact and form a common interface, then the difference in their wetting tensions Δj, the so-called oil-displacement tension, is effective along the line of contact. In addition, a portion of the interfacial tension γ_{AB} remains effective along the substrate surface, but with reversed sign and a magnitude of $\gamma_{AB} \cos \theta$, where θ is the contact angle in the oily phase B. The total force that results is the contact tension R, given by Equation 5.

$$R = \Delta j + \gamma_{AB} \cos\theta \quad (5)$$

The contact tension acts in such a direction as to constrict the oil drop. As a result of adsorption of surfactants from phase A, the value

of Δj is increased and that of γ_{AB} is decreased. The value of γ_{AB} cos θ is negative for obtuse contact angles. From Equation 5, it can be seen that both quantities contribute to an increase in the contact tension and thus to better penetration of the oil drop. This complex process, in which a surface undergoes wetting first by oil and then by water, is known as rollup. For many cases of practical interest, rollup is not a spontaneous phenomenon. More often, total constriction of an oil drop can be achieved only if mechanical energy is applied to the system. The required energy is directly proportional to the interfacial tension γ_{AB} and decreases with increasing surfactant concentration. The process is shown in Figure 26 [78].

Figure 26. Schematic view of the phases of displacement of an oily drop B by a detergent A

All the relationships presented thus far confirm the premise that interfacial tension is the primary force resisting the removal of liquid soils, and this force must be minimized if the washing process is to be effective.

Figure 27. Dynamic interfacial tension of $C_{12/14}$ fatty alkyl sulfate (FAS) and linear alkylbenzenesulfonate (LAS) as a function of time for decane and 2-octyldodecanol (top) and isopropyl myristate (IPM) (bottom)

Findings such as these are independent of the nature of the fiber and apply to all soils containing hydrophobic particles and oily material [79]. The oil specificity of surfactants is very important for the use in different applications [80]. Figure 27 shows the interfacial tension of (linear) alkylbenzenesulfonate (LAS) and of a fatty alcohol sulfate ($C_{12/14}$ FAS) against three different oils [81]. Both surfactants show nearly identical interfacial tension against decane and 2-octyldodecanol. In contrast the interfacial tension of FAS against isopropyl myristate is significantly lower than that of LAS. As a result, most commercial detergents contain mixtures of surfactants in carefully determined proportions. The interfacial tension in detergents is a measure of their product performance. This is shown by way of example for five different heavy-duty detergents in Figure 28 [80].

Oil-removal values also reach their upper limit at the critical micelle concentration of the surfactant employed [82]. This is illustrated in Figure 29 for the example of removing olive oil from wool.

Figure 28. Interfacial tension of different detergents (A to E) against mineral oil [80]

Figure 29. Removability of an olive oil–oleic acid mixture from wool, shown as a function of sodium *n*-dodecyl sulfate concentration for various degrees of oil coating (c_M=critical micelle concentration) [82]
a) 4.6 % Oil coat; b) 3.3 % Oil coat; c) 2.2 % Oil coat

From this behavior it can be concluded that effective washing is a result of the properties of individual surface-active ions, not of micelles. Just as with emulsification, however, micelles are able to solubilize water-insoluble materials and thereby prevent redeposition of previously removed soil in the later stages of the washing process. Values reported in the literature for critical micelle concentrations are based on pure solutions of surfactant. However, in an actual washing process, surfactants are invariably adsorbed onto a variety of surfaces, which means that the true surfactant concentration in the wash liquor is correspondingly diminished. The true surfactant concentration in solution is the only significant measure.

One way to reduce the interfacial tension is to create appropriate mixed adsorption layers comprised of surfactants of differing constitution. For example, Figure 30 shows the interfacial tension of the system water–toluene as a function of composition for a surfactant mixture containing the anionic surfactant sodium *n*-dodecyl sulfate (SDS) and the nonionic surfactant hexadecyl triglycol ether ($C_{16}E_3$), whereby the total surfactant concentration is kept constant [83].

Figure 30. Interfacial tension after 10 min and after equilibrium vs. composition of the mixture (organic phase toluene, concentration 0.5 g/L, pH = 10, T = 298 K) [83]

Even small additions of one surfactant to another may cause a significant reduction in the interfacial tension. In a broad concentration range mixtures of these surfactants show lower values of interfacial tension than the two surfactants alone. The presence of a small amount of nonionic surfactant in the surface layer reduces the mutual repulsion of negatively charged groups on the anionic surfactant, as a result of which adsorption increases. A quantitative relationship for the surface activity and the CMC for surfactant mixtures was derived by Rosen [84]. The CMC of a mixture can be described by the following equations with β as the interaction parameter:

$$\frac{1}{\mathrm{CMC_{mix}}} = \frac{\alpha}{f_1\,\mathrm{CMC_1}} + \frac{1-\alpha}{f_2\,\mathrm{CMC_2}} \tag{6}$$

$$f_1 = \exp \beta[1-x_1]^2 \tag{7}$$

$$f_2 = \exp \beta\, x_1^2 \tag{8}$$

For an attractive (synergistic) interaction the parameter β is negative, and for repulsion β is positive. The attractive interaction leads to a lower CMC of a specific surfactant mixture compared to the ideal case (Fig. 31).

Figure 31. Critical micelle concentration of mixtures of an anionic surfactant $C_{12}SO_4Na$ and a nonionic surfactant $C_{16}E_3$ as a function of the mole fraction α of nonionic surfactant in comparison to ideal behavior of the mixtures [83]

Phase Behavior Phase behavior can have a significant impact on detergency [85]. If there is no phase change for the surfactant water system, a linear dependence of the cleaning efficiency on temperature is observed, which is shown as an example for household detergents in Figure 32. The surfactant is in an isotropic micellar solution at all temperatures. The cloud point of the surfactant used here is 85 °C at the given concentration (2 g/L), i.e., above the highest washing temperature.

Figure 32. Phase behavior of $C_{12}E_9$ and household detergency [85]

Tests with other pure ethoxylated surfactants have revealed that a discontinuity is observed with respect to oil removal versus temperature in cases where dispersions of liquid crystals exist in the binary system water–surfactant. Figure 33 shows that the detergency values for mineral oil and olive oil, i.e., two oils with significantly different polarities, are at different levels. It also demonstrates that in both cases a similar reflectance versus temperature curve exists. In the region of the liquid-crystal dispersion, i.e., between 20 and 40 °C, oil removal increases significantly. Above the phase transition $W + L_\alpha \rightarrow W + L_3$, between 40 and 70 °C, no further increase in oil removal takes place. For olive oil, a small decrease in detergent performance is observed. The interfacial tensions between aqueous solutions of $C_{12}E_3$ and mineral oil lie at about 5 mN/m at 30 and 50 °C. These relatively high values indicate that in this system the interfacial activity is not the decisive factor in oil removal from fabrics. The macroscopic properties of the liquid-crystal dispersion seem to be responsible for the strong temperature dependence. It can be assumed that fragments of liquid crystals are adsorbed onto fabric and oily soil in the $W + L_\alpha$ range during washing. The local surfactant concentration is therefore substantially higher in comparison to the molecular surfactant layer that forms when surfactant monomers adsorb. As the viscosity of liquid crystals in the single-phase range is strongly temperature dependent, it can be assumed that the viscosity of a fragment of a liquid crystal deposited on a fabric also significantly decreases with increasing temperature. Thus, the penetration of surfactant into the oil phase and removal of oily soil is promoted.

Figure 33. Phase behavior of the polyoxyethylene alcohol $C_{12}E_3$ and detergency (2 g/L surfactant) [85]

Technical-grade surfactants are of specific interest for applications. As in the case of pure nonionic surfactants, definite ranges for technical-grade surfactants exist in which there is only a

slight dependence of oil removal on temperature (Fig. 34). For $C_{12/18}E_5$, this is in the range of the two co-existing liquid phases (W + L_1), and for $C_{12/18}E_4$ it is in the range of the surfactant liquid phase (W + L_2). An unusually strong increase of oil removal with increasing temperature occurs in the region of the liquid-crystal dispersion (W + L_α). At 30 and 50°C the interfacial tensions between aqueous surfactant solutions and mineral oil and the contact angles on glass and polyester were determined for $C_{12/18}E_4$. Whereas the values of interfacial tensions are practically identical (ca. 0.1 mN/m) the contact angles on both substrates are slightly less advantageous at higher temperatures. Hence, the increased oil removal between 30 and 50 °C cannot be attributed to an increase in the adsorbed amounts of surfactants. Rather in both cases, the decisive part is probably played by the macroscopic properties of the liquid crystal dispersion and their temperature dependence.

Figure 34. Phase behavior of the polyoxyethylene alcohols $C_{12/18}E_4$ and $C_{12/18}E_5$ and detergency [85]

During oil removal from hard surfaces or fabrics ternary systems occur in which three phases coexist in equilibrium. These systems are also referred as three-phase microemulsions. These effects were studied in detail for alkyl polyglycol ethers [86]. Depending on temperature different phases exist, having a three-phase region between the temperatures T_l and T_u. When these three phases are formed, extremely low interfacial tensions between two phases are observed. Figure 35 (bottom) represents the three-phase temperature intervals for $C_{12}E_4$ and $C_{12}E_5$ versus the number *n* of carbon atoms of *n*-alkanes. The top part of Figure 35 shows the detergency of these surfactants for hexadecane. Both parts of Figure 35 indicate that maximum oil removal occurs in the three-phase interval of the oil used (*n*-hexadecane) [87].

Figure 35. Detergency of $C_{12}E_4$ and $C_{12}E_5$ against hexadecane as a function of temperature (left) and the corresponding three-phase ranges for these surfactants as a function of the number *n* of carbon atoms of alkanes [87]

This means that not only the solubilization capacity of the concentrated surfactant phase, but probably also the minimum interfacial tension existing in the range of the three-phase body are responsible for maximum oil removal. Further details about the influence of the polarity of the oil, the type of surfactant, and the addition of salt are summarized in [88].

Studies of diffusional phenomena have direct relevance to detergency processes. Experiments are reported which investigate the effects

of changes in temperature on the dynamic phenomena which occur when aqueous solutions of pure nonionic surfactants contact hydrocarbons such as tetradecane and hexadecane. These oils can be considered to be models of nonpolar soils such as lubricating oils. The dynamic contact phenomena, at least immediately after contact, are representative of those which occur when a cleaner solution contacts an oily soil on a polymer surface. With $C_{12}E_5$ as the nonionic surfactant at 1 wt % in water, quite different phenomena were observed below, above, and well above the cloud point when tetradecane or hexadecane was carefully layered on top of the aqueous solution. Below the cloud point temperature of 31 °C, very slow solubilization of oil into the one-phase micellar solution occurred. At 35 °C, which is just above the cloud point, a much different behavior was observed. The surfactant-rich L_1 phase separated to the top of the aqueous phase prior to the addition of hexadecane. On addition of the oil, the L_1 phase rapidly solubilized the hydrocarbon to form an oil-in-water microemulsion containing an appreciable amount of the nonpolar oil. After depletion of the larger surfactant-containing drops, a front developed as smaller drops were incorporated into the microemulsion phase.

Unlike the experiments carried out below the cloud point temperature, appreciable solubilization of oil was observed in the time frame of the study, as indicated by upward movement of the oil–microemulsion interface. Similar phenomena were observed with both tetradecane and hexadecane as the oil phases. When the temperature of the system was raised to just below the phase inversion temperatures of the hydrocarbons with $C_{12}E_5$ (45 °C for tetradecane and 50 °C for hexadecane), two intermediate phases formed when the initial dispersion of L_1 drops in water contacted the oil. One was the lamellar liquid-crystalline phase L_α (probably containing some dispersed water). Above it was a middle-phase microemulsion. In contrast to the studies below the cloud point temperature, there was appreciable solubilization of hydrocarbon into the two intermediate phases. A similar progression of phases was found at 35 °C with *n*-decane as hydrocarbon. At this temperature, which is near the phase-inversion temperature of the water–$C_{12}E_5$–decane system, the existence of a two-phase dispersion of L_α and water below the middle-phase microemulsion was clearly evident. These results can be utilized to optimize surfactant systems in detergents, and in particular to improve the removal of oily soils. The formation of microemulsions is also described in the context of the pretreatment of oil-stained textiles with a mixture of water, surfactants, and cosurfactants.

Besides cleaning efficiency the liquid-crystalline phases of surfactant systems at higher concentrations are of crucial importance for the processing of concentrated surfactant systems and the formulation as well as the application of liquid products. Studies of phase behavior can be supported by computer simulations, which can predict the liquid-crystalline phases [89].

Figure 36. Schematic drawing of the effect of liquid flow on adhering particles of different size
u Flow velocity; *d* Distance from the solid surface

2.4.3. Particulate Soil

For solid soil particles above a certain size hydrodynamic effects are advantageous for soil removal [90]. The significance of hydrodynamic effects in the removal of particulate soil from fibers decreases with decreasing particle size. Even with vigorous mechanical action, a laminar film of finite thickness in which no flow takes place is present on every surface. The flow velocity gradient increases with increasing distance from the surface, as shown schematically in Figure 36.

Thus, an increase in mechanical force has a significant soil-removing effect on larger particles. A high flow velocity gradient in the immediate vicinity of a surface is excluded for hydrodynamic reasons. Therefore, washing machines

employ abrupt changes in direction of operation to achieve adequate turbulence near substrate surfaces. Even so, particles smaller than 0.1 μm cannot be displaced by mechanical means alone.

For the effective removal of solid particles below this size, adsorption of surfactants on the particle surface and stabilization of the particles in the washing solution are the most important steps. Concerning the stability of dispersed solid particles, charge effects play a major role. Different surfaces may have different surface charges. Through the adsorption of surfactants on the surfaces the charge effects may change and the particle are stabilized by electrostatic effects.

The electrostatic stabilization of such a dispersion is not only dependent on surfactant adsorption, but also on salt concentration and the pH of the washing solution. Dispersions can also be stabilized by other mechanisms, e.g., steric stabilization or stabilization through depletion. However, these mechanisms are not treated here.

Figure 37. Calculated potential energy of attraction P_A and repulsion P_R as a function of the distance of a particle from a fabric, along with the resultant potential P; predictions based on the DLVO theory
DLVO computational parameter $z = 4$ [93]

Derjaguin–Landau–Verwey–Overbeek theory (DLVO). A theoretical understanding of the interaction forces causing a solid particle to adhere to a more or less smooth surface is based on the Derjaguin–Landau–Verwey–Overbeek (DLVO) theory [91, 92]. Since this theory was developed to explain the phenomena of flocculation and coagulation, however, it can be applied to the washing process only in modified form [93]. A plot of potential energy as a function of the distance of a particle from a fabric shows that the potential energy passes through a maximum (Fig. 37).

The minimum in the potential energy curve corresponds to the closest possible approach, i.e., to the minimum distance that can be established between the particle and the fiber. The maximum is a measure of the potential barrier that must be overcome if the particle either is removed from the fiber or approaches the fiber from a distance. Adhering particles are more easily removed if the potential barrier is small. Conversely, a soil particle already in the wash liquor is less likely to establish renewed contact with the fabric if the potential barrier is large.

With respect to the washing process, if a particle is bound to a fabric, only a single common electrical double layer located at the overall external surface exists initially. None is present within the zone of contact. During the washing process, new diffuse double layers are created which cause a reduction in the free energy of the system. The free energy of an electrical double layer is a function of distance and diminishes asymptotically to a limiting value that corresponds to a condition of no interaction between two double layers. Twice as much effort must be expended to bring a particle into contact with a substrate because of the presence on both surfaces of a double layer (curve 2 F in Fig. 38). The separation of two adhering surfaces is characterized initially only by van der Waals–London attractive forces P_A and Born repulsion forces P_B, since at this point no electrical double layer exists [93]. In Figure 38, the equilibrium condition corresponding to the potential energy minimum has been taken as the zero point on the abscissa. With increasing distance between the particle and the contact surface, a diffuse double layer arises, which assists in the separation process by establishing an element of repulsion. Thus, the true potential curve P for the sepa-

ration of an adhering particle in an electrolyte solution results from a combination of the van der Waals–Born potential and the free energy of formation of the electrical double layer. The important conclusion from Figures 37 and 38 is that an increase in the potential of the electrical double layer increases the energy barrier for particle deposition but decreases that for particle removal.

A schematic representation of the adsorption layers on substrate and soil particles is shown in Figure 39. As can be seen from the diagram, both surfactant layers advance to the point of particle–surface contact. One consequence is the development of a disjoining pressure, which leads to separation of the soil particle from the surface. This effect is obviously present with anionic surfactants as well. However, this pressure is the decisive factor with nonionic surfactants, due to the absence of any repulsive components of electrostatic origin.

Figure 38. Potential energy diagram for the removal of an adhering particle [61]

Figure 40 shows the effect of several aqueous surfactant solutions on the surface potential of carbon black [61]. The surfactants chosen for the study all share the same hydrophobic component, but their hydrophilic groups vary. Electrophoretic mobility (EM) is taken as a measure of surface potential in this case.

Figure 39. Schematic representation of adsorption-induced separation of a spherical particle from a hard surface
S Surface; P Particle; Π_S Splitting pressure of the surfactant layer on the surface; Π_P Splitting pressure of the surfactant layer on the particle [93]

Carbon black acquires a negative charge in water. The negative charge of pigments and fibers is further increased by adsorption of anionic surfactants. The corresponding increase in mutual repulsion is responsible for an increase in the washing effect. Dispersing power for pigments also increases for the same reason, whereas the redeposition tendency of removed soil is diminished.

In contrast to anionic surfactants, cationic surfactants reduce the magnitude of any negative surface charge. Consequently, electrostatic attraction between soil and fabric is increased. For this reason, cationic surfactants may cause a decrease in washing effect below that observed with pure water. Significant soil removal then occurs only at high surfactant concentrations, at which a complete charge reversal takes place on both fabric and soil. When the laundry is rinsed, however, a second charge reversal takes place on the fabric. At the point of electrical neutrality, redeposition of previously removed pigment soil is observed. This is why cationic surfactants are less suited for use in detergents than anionic surfactants.

Figure 40. Electrophoretic mobility (EM) of carbon black in solutions containing various surfactants at 35 °C [61]

a) $C_{14}H_{29}OSO_3Na$ (anionic);
b) $C_{14}H_{29}O\ (CH_2CH_2O)_9H$ (nonionic);
c) $C_{14}H_{29}N\ (CH_3)_3Cl$ (cationic)

The negative influence exerted by calcium ions originating from water hardness can also be explained with the help of potential theory. According to the Schulze–Hardy rule, compression of an electrical double layer increases rapidly as the valence of a cation increases. Therefore, high concentrations of calcium might cause attractive forces to become the dominant factor, leading to significantly lower washing efficiency than would be achieved in distilled water.

Addition of an electrolyte generally leads to compression of the electrical double layer between two hard surfaces. Because the surface potentials cannot be measured directly, the zeta potential or electrophoretic mobility of a particle is used as a measure of its surface charge. The zeta potential can be defined as the potential difference in the electrical double layer at a shear plane between the fairly immobile layer on the surface of the particle and the diffuse layer outside the slipping plane when the solid and liquid phases are moved tangentially to each other. The zeta potential is a good indicator of the magnitude of the repulsive interaction between colloidal particles and is very strongly dependent on the electrolyte concentration in the solution. As the indifferent-electrolyte concentration increases, the zeta potential decreases and a sharply defined coagulation concentration can be identified. This is the point at which the potential energy barrier opposing coagulation disappears, and hence coagulation takes place (critical coagulation concentration, CCC). To prevent agglomeration a sufficient potential (Fig. 41) should exist, and the concentration of indifferent electrolyte should not exceed a certain level [94].

Figure 41. Total potential energy of interaction between flat plates of kaolinite as a function of separation at pH 10.4 for various electrolyte concentrations [95] (cited in [94])

Generally, fibers and pigments in an aqueous medium acquire negative charges, whereby the extent of charge increases with increasing pH. This is illustrated in Figure 42, in which the zeta potential of various fibers is taken as a measure of electrical charge and is plotted against pH [90].

Essentially similar results are obtained for all major particulate soil components. This is one of the reasons for enhancement of wash performance by mere introduction of alkali. However, repulsive forces between soil and fibers alone are insufficient to produce satisfactory washing even at high pH.

The dependence of the surface charge of TiO_2 particles on pH in salt solutions of various concentrations is shown in Figure 43 [94]. At pH 5.8 the surface has zero charge. Below pH 5.8, the particles have positive surface charge, while they have a negative surface charge above pH 5.8. The point of zero charge is characteristic for the particular metal oxide. The influence of the electrolyte concentration on the absolute value of the surface charge is also obvious from Figure 43.

Figure 42. ζ Potential of various fibers as a function of pH [90]
a) Wool; b) Nylon; c) Silk; d) Cotton; e) Viscose

Figure 43. Typical examples of surface charge/pH behavior for TiO_2 in KNO_3 solutions in an inert atmosphere at 25 °C [96] (cited in [94])

From the theories of double layers it follows that the distribution of the countercharge also changes when the salt concentration is increased, to promote accumulation of charge in the region close to the surface. This explains the increase in positive charge with increasing salt concentration at low pH values. If specific adsorption of one of the ions of the electrolyte takes place on the particle surface, the picture is basically changed. Such ion adsorption may influence the position of the point of zero charge. Strong specific adsorption of ions on the particle surface leads to increased shift of the point of zero charge. Hence, salt concentration, pH value, and the resulting degree of surface charge of the particles play a major role in the electrostatic stabilization of particulate soil.

2.4.4. Chemical Reactions

2.4.4.1. Bleachable Stains

For the effective removal of colored stains like tea, coffee, red wine, and fruit juices chemical changes of the colored substances are necessary. This can be achieved by oxidation of the active groups or double bonds of the colored substances. This kind of oxidative bleaching will be performed with chlorine or oxygen bleaches. Oxygen bleach is the most common in Western Europe because the only byproduct after bleaching is water.

Figure 44. Schematic representation of possible chemical changes of substrates upon oxidation with H_2O_2 and an oxidation catalyst [97]

Most colored stains are relatively large conjugated molecules. Epoxidation of a double bond is one of the most typical chemical changes on oxidative bleaching. An epoxide is formed which can transform into an alcohol (Fig. 44).

Thus, the conjugated systems are destroyed and the molecule loses its color, although in many cases it still adheres to the fabric.

Figure 44 shows some of the chemical changes which can be expected to occur upon oxidative bleaching of colored stains [97].

H_2O_2. The most common source of active oxygen for oxygen bleach is H_2O_2, usually in the form of perborate or percarbonate. These can set free H_2O_2 spontaneously at higher temperatures during the washing process. The H_2O_2-releasing mechanism of percarbonate is illustrated below.

$$2\,Na_2CO_3 \cdot 3\,H_2O_2 \rightarrow 2\,Na_2CO_3 + 3\,H_2O_2 \qquad (9)$$

There are many theories about the active species of H_2O_2 bleaching. Mostly the HOO^- anion at higher pH values [98] or the superoxide radical $O^{\cdot 2-}$ [99, 100] are held responsible for the bleaching reaction. However, it is well known that the H_2O_2 bleaching process is most effective at temperatures of 60 °C and higher.

The mechanism for formation of radicals upon bleaching with H_2O_2 is suggested to be [100]:

$$HO_2^- + H_2O_2 \rightarrow HO_2^{\cdot} + HO^- + HO^{\cdot} \qquad (10)$$

The radicals are said to be responsible for the bleaching reaction. The pH dependence of the bleaching as percentage stain removal is shown in Figure 45. The bleaching efficiency reaches its maximum at a pH value of about 11. This corresponds to the pK_a value of H_2O_2, which is 11.7 at 25 °C.

Figure 45. Relative stain removal (% SR) after 60 min of bleaching with H_2O_2 at 60 °C and different pH values [100] ○ = 6.5 × 10^{-3} mol/L H_2O_2 in buffer solution. Scavenging test with ■ = 10^{-3} mol/L 4-nitroso-N,N-dimethylaniline, ● = 10^{-3} mol/L potassium hexacyanoferrate (11)

Figure 46. The two most common bleach activators TAED and SNOBS

Activators. To achieve higher bleaching efficiency at lower temperatures a bleaching activator like tetraacetylethylenediamine (TAED, Europe) or *p*-nonanoyloxybenzolsulfonate (SNOBS, USA; Fig. 46) can be added in combination with percarbonate or perborate [101].

By reaction with H_2O_2, tetraacetylethylenediamine forms two moles of peracetic acid per mole of TAED. The peracetic acid is active at lower temperatures than the H_2O_2 itself. The combination of H_2O_2 and peracetic acid enables effective bleaching over a broad range of temperatures. SNOBS reacts with H_2O_2 to form pernonanoic acid, which has similar advantages to peracetic acid.

The reaction with H_2O_2 to form a peracid under alkaline conditions is shown in Figure 47 [102]. The rate of peracetic acid formation increases with increasing pH value of the solution.

Figure 47. Mechanism for the transformation of H_2O_2 into a peracid by using an activator [101]

The kinetics of the transformation of H_2O_2 into peracetic acid is shown in Figure 48 [102].

The mechanism of bleaching with a peracid can occur by a nucleophilic mechanism at pH values above the pK_a of the peracid, and by an electrophilic mechanism at pH values below the pK_a value of the peracid. This is shown schematically in Figure 49 [103].

Figure 48. Time course of the reaction of TAED and H_2O_2, showing the formation of peracetic acid as a function of time at pH 9.6. ○ = peracetic acid, □ = H_2O_2, △ = peracetic acid plus H_2O_2 [102].

Figure 49. Reaction mechanism for bleaching with a peracid at pH values above and below the pK_a value of the peracid [103]

The bleaching efficiency of a peracid as a function of the pH value of the washing liquid is shown in Figure 50. The bleaching efficiency reaches its maximum at pH values close to or slightly above the pK_a value of the peracid, and collapses at pH values higher than this. The pK_a value of peracetic acid is 8.2, which corresponds to its maximum bleaching performance.

Peracids need not necessarily be formed in situ. They can also be directly included in the formula without extra addition of H_2O_2. However, few effective and stable peracids are commercially available, and hence the application of peracids in detergent formulations is not common.

Figure 50. Bleaching performance of peracid in dependence on the pH value for tea and red wine stains [104]

Decomposition of H_2O_2 or Peracid. The decomposition of hydrogen peroxide can proceed spontaneously or catalytically.

Autoxidation of H_2O_2 to water and oxygen (Eq. 11) is an exothermic process. At higher temperatures this reaction takes place quickly, but at room temperature it is relatively slow, and hence H_2O_2 can be regarded as stable at room temperature.

$$2\,H_2O_2 \rightarrow 2\,H_2O + O_2 \tag{11}$$

pH, light, and traces of metal ions as catalysts can influence the inefficient decomposition of hydrogen peroxide. In this case decomposition proceeds by a radical mechanism, in which the free radicals from Equation 10 function as chain propagators [100].

$$HO^{\cdot} + H_2O_2 \rightarrow H_2O + HO_2^{\cdot} \tag{12}$$

$$H_2O_2 + HO_2^{\cdot} \rightarrow H_2O + O_2 + HO^{\cdot} \tag{13}$$

Decomposition of peracids, however, leads to the formation of the corresponding carboxylic acids, which are not bleach-active.

Catalytic Bleaching with H_2O_2. Using a metal catalyst in addition to H_2O_2 can lead to even better bleaching efficiency at lower temperatures. Although the mechanism of the catalyzed bleaching reaction is not fully understood, the most common opinion in the literature is that the transition metal complex forms a metal oxo intermediate with the active oxygen species (H_2O_2) [103]. The metal is hereby oxidized to a higher state. On oxidation of a substrate by the metal oxo intermediate, the metal returns to its original oxidation state. Cleavage of the metal–oxo bond can take place via a homolytic or a heterolytic path. In the case of homolytic cleavage radicals are formed and the further mechanism is radical. In the case of heterolytic cleavage a nonradical mechanism takes place.

Stability to hydrolysis in alkaline solution is one of the main problems concerning most of the catalysts suggested in the literature. This is a problem especially for manganese and iron catalysts. On hydrolysis, water-insoluble MnO_2 and Fe_2O_3 are formed, which are inert in the bleaching reaction.

Fiber care is another important problem concerning catalytic bleaching with H_2O_2. Until now, high catalyst performance has been associated with high fiber damage. This has been a restriction for the general use of catalysts in detergents until now.

2.4.4.2. Enzymatic Soil Removal

Detergent compositions usually contain several different kinds of enzymes. Generally, the action of the enzymes is to cleave large biological polymers such as proteins in natural stains and to make their subsequent removal by other detergent components easier. Enzymes are very selective biological catalysts, and hence one particular class of enzyme can cleave one particular class of biopolymer.

One of the most common enzymes in detergent formulations is protease, which is especially active in the degradation of proteins and polypeptides. Cellulases are responsible for the cleavage of amorphous cellulose, as in vegetable- and fruit-based stains, whereas amylase degrades starch and helps to remove starch-based soils like flour- or potato-based stains. Lipase hydrolyzes the ester bonds of natural animal and plant fats [105, 106].

Enzymes typically show a maximum efficiency at a certain pH value and a certain temperature. To optimize the efficiency it is important that the maximum performance is within the range of the normal detergent parameters. The typical performance maximum in dependence on the pH value of an amylase is shown in Figure 51 [107].

Figure 51. pH–activity profiles for amylase [107]

As the subject of this article is the physical chemistry of the washing process, the mechanism of enzyme activity will not be explained further here. More detailed information about the enzyme mechanism in detergents can be found elsewhere [105 – 108] (see also → Enzymes, Section 5.2.1).

2.4.5. Soil-Repelling Effects

Generally it is desired that fat and pigment soils which have been removed from the textile surface are not redeposited on the textile surface during the washing process. As a result of redeposition the textiles may appear somewhat gray after several wash cycles. To prevent the redeposition of such soils several effects play a role. Once removed from the surface the soil must be stabilized in solution. At the same time the surface can be treated to prevent soil from adhering to the surface again. This may lead to the long-term effect that soil is generally less firmly fixed to the surface and can be more easily removed during the next washing cycles. These effects are also known as soil-repellent effects. The easiest way to achieve soil-repellent performance is to add a soil-repelling agent to the

washing formulation. These are mostly polymers, and may work by one of many mechanisms. The most important substances increase the electrostatic repulsion of soil molecules or bind the molecules into a polymer matrix in the solution [109]. Other possibilities to achieve a soil-repellent effect are different kinds of textile pretreatment. The common goal for both pretreatment and most detergent-delivered soil-release agents is a polymeric molecular layer which covers the fibers of the textile and modifies its surface characteristics.

In a surfactant-free environment, the adsorption of most macromolecules onto a solid surface is effectively an irreversible process. The reason for this irreversibility is the vast number of points of contact that exist between macromolecule and substrate. From a statistical standpoint, the number of bonds between the two is so large that adherence is ensured regardless of the strength of the bonds. Most of the observed binding results from weak hydrophobic interactions.

In a multicomponent system containing both surfactants and macromolecules, competitive adsorption is possible at the substrate surface. This permits the surfactant to successively destroy the individual points of contact binding the macromolecule, thereby displacing it from the interface. This mechanism is most often observed for nonionic surfactants. Anionic surfactants are often capable of forming polymer–surfactant complexes, in the course of which the conformation of the macromolecule is altered in such a way as to reduce the extent of its attraction to the interface.

Cotton and synthetic fibers such as polyester have very different surface characteristics. Whereas cotton is hydrophilic and negatively charged in water at alkaline pH values, synthetic fibers are comparatively neutral. The affinity of hydrophobic oils and greases is therefore higher to the hydrophobic polyester surface then to the hydrophilic cotton surface. Oil and grease wet the synthetic textile surface comparably well and make the rolling up process of oil removal more difficult. Through adsorption of a soil-release agent the surface characteristics are changed to more hydrophilic, and hence the soil removal process is made easier. On a more hydrophilic surface the affinity of hydrophobic soils is less strong and water can penetrate better into the fabrics and between the soil and the modified surface. Because of this, different soil-release agents should be chosen for cotton and for synthetic fibers. In fact up to now there are more effective soil-release agents for synthetic fibers than for cotton. The absolute amount of polymer adsorbed on the surface is therefore mostly not the determining parameter [110].

Polymers or nanoparticles can be added to the surface of textiles during production and lead to soil-repellent qualities which are said to be retained for several washes. For example, nanosized whiskers aligned by proprietary spines, designed to repel hydrophobic or hydrophilic liquids, can be attached to the fabrics during production [111]. Another example of soil repellency through pretreatment is the use of plasma technology to modify or to apply a thin polymer layer to the cotton surface [112, 113]. By using radio-frequency plasma, chemicals such as fluorocarbons can be activated and polymerized on the surface of the textile. Ar, O_2, air, and NH_3 gas plasma treatments have been shown to increase the wettability of the cotton surfaces, whereas fluorinated gas plasma leads to a decrease in water adsorption. This treatment generates more hydrophobic surfaces [113].

Figure 52. Dynamic contact angles for knitted fabric after soiling and washing with and without pretreatment with a soil-release polymer. (○) untreated; (●) after treatment with a soil-release polymer, only one value recorded; (▥) stained after treatment; (■) washed after treatment and staining; (△) stained without treatment; (▲) washed after staining without treatment [114]

A new method to visualize the soil-release polymer on the textile surface and its influence on the degree of soiling has been developed [114, 115]. The visualization of the transparent

film was achieved with an imaging instrument operating on the principle of chromatic aberration. Water contact angles before and after impregnation of different polyester fabrics with a polyether—polyester soil repellent polymer are shown in Figure 52 [114]. The contact angle changes to small values after impregnation, and this enables water to penetrate into the textile.

The residual soil degree could be evaluated and the relative cleaning performance calculated. If the fabrics are washed after impregnation prior to staining, the effect is much less. It is suggested that the polymer film shields the fabric against soil, and that the soil protects the impregnation from being washed out.

Some further examples of soil-release polymer are acrylate polymers and terephthalate polyesters. Polyacrylate films may be deposited onto the surface and then cured in the presence of a diepoxy compound. This leads to a cross-linked polymer film which inhibits soil deposition. When a terephthalate polyester is used as soil-release polymer the aromatic/glycol groups orient themselves to the polyester fabric surface while the ethylene oxide blocks of the polymer are oriented into the solution and hinder the soil from coming into contact with the fiber surface. Adsorbed polyester can form a hydrophilic film which remains on the fabric after it is removed from the wash solution and dried. Upon washing with detergent compositions containing the soil-release polymer the film is renewed. Hence, the soil-release effect of this polymer class increases after several washing cycles [109].

For cotton other soil-release polymers, e.g., carboxymethyl cellulose, are more effective. To ensure satisfactory results with mixed laundry, combinations of several antiredeposition agents often must be used.

Figure 53 reveals clear differences in the time-dependent increase in weight when prewashed polyester is immersed in water [80]. The polyester fibers had previously been washed with different detergent formulations. Table 9 shows that carboxymethyl cellulose, a frequently used antiredeposition agent for cotton, has no effect on polyester. By contrast, methylhydroxypropyl cellulose and soil repellents cause the polyester surface to become considerably more hydrophilic. It is noteworthy that the effects are retained with both detergents, albeit to a somewhat reduced extent. Only with these formulations is a significant increase in the soil antiredeposition effect observed, as evidenced by the changes in percentage remission. Hydroxyethyl cellulose can be regarded as a representative of numerous polymers which, though they are readily adsorbed from aqueous solutions and are capable of showing considerable antiredeposition activity in pure water, nonetheless loose most of their effectiveness in a detergent solution as a result of competitive adsorption and displacement by surfactants.

Figure 53. Kinetics of wetting of polyester fibers by three different detergents. The increase in weight of the fibers during wetting by pure water is plotted as a function of the wetting time [80]

2.5. Formulation

2.5.1. Foam

The control and adjustment of the foam properties is essential for all washing and cleaning processes. Depending on the product either the formation of high and stable foam is desired or low foam is absolutely necessary. From a physicochemical point of view the generation and stabilization of foam depends on several parameters (Fig. 54).

The diffusion of the surfactants into the newly formed interface is an important parameter for foam formation. A faster diffusion of the surfactant into the surface and the incorporation into the surface layer facilitates the stabilization of the foam bubbles. The dynamic surface tension is a suitable parameter to characterize this effect. This was studied for different types of surfactants [54]. A correlation was derived between

Table 9. Comparison of changes in polyester wetting tensions with changes in remission for a heavy-duty detergent (I) and a low-temperature heavy-duty detergent (II) for polyester

		Antiredeposition agent (in % detergent charge)			Change in wetting tension*		Change in remission**

the relative dynamic surface pressure $\Pi(t)$ according to Equation 14 and the foam formation for standard conditions (Fig. 55).

$$\Pi\,(t)\,/\,\Pi_{\mathrm{eq}} = [\sigma_{\mathrm{water}} - \sigma\,(t)]\,/\,(\sigma_{\mathrm{water}} - \sigma_{\mathrm{eq}}) \qquad (14)$$

Figure 54. Foaming of surfactant–water systems: correlation of experimental data with physical chemical parameters

The diagram clearly shows the importance of dynamic effects of the surfactant solution regarding diffusion behavior for the formation and stabilization of newly generated foam bubbles.

Foam control and defoaming effects are specific aspects of detergents especially important for washing machines. A schematic of the defoaming mechanisms is shown in Figure 56. For a liquid defoamer principally two mechanisms are possible. Either the defoamer spreads on the surface or it forms a droplet. In the case of spreading, the foam lamella becomes thinner and finally disrupts. A defoamer droplet forms a bridge within the foam lamella, which also leads to film rupture. In a similar way hydrophobic defoamer particles perform.

Figure 55. Correlation between relative dynamic surface pressure and foam formation dh/dt for different surfactants [57]

Figure 56. Schematic of defoaming mechanisms

2.5.2. Microemulsions

The spontaneous formation of microemulsions from aqueous surfactant systems and oily soils during the washing process was already mentioned in Section 2.4.2, but microemulsions can also be used as a washing liquid [116]. Solans et al. [117] published studies of textile cleaning with microemulsions. At washing temperatures between 23 and 34 °C, homogeneous microemulsions obtained from the system water/C_{12} - E_4/n-hexadecane and systems with technical nonionic surfactant mixtures removed 1.5 to 2 times more soil from wool, cotton, and cotton–polyester blended fabrics stained with oily and particulate soils than a highly concentrated liquid detergent (Fig. 57). Soil removal by the microemulsions was increased by 20 to 25 % by adding 0.05 M of the electrolytes sodium triphosphate and sodium citrate, which act as builders. The microemulsions also proved superior to the liquid detergent, in that they could be used seven times without losing any of their cleaning effectiveness. Förster et al. [116] systematically describe the phase behavior of quaternary systems, consisting of water, nonionic surfactants, a cosurfactant, and a hydrocarbon, also with regard to possible applications in textile cleaning.

Figure 57. Soil removal *S* by a surfactant phase microemulsion (ME) and by a 1 % aqueous liquid detergent solution (L. Det) from different fabrics [117]

2.5.3. Phase Stability

The phase behavior of surfactant systems not only has an influence on the soil removal process, but also on the viscosity and stability of the detergent formulation. The phase behavior of a binary mixture of an anionic surfactant in water is dependent on the concentration of the surfactant and the temperature and is shown for a C_{14} fatty alcohol sulfate in Figure 58 [81]. At low concentrations a micellar phase appears. With increasing concentration it changes into a hexagonal phase and at even higher concentrations into a lamellar phase. With increasing alkyl chain length, the solubility of the surfactant shifts to higher temperatures, while the hexagonal phase becomes broader. The hexagonal phase is characterized by a maximum in viscosity and yield value, as shown in Figure 59 [81]. The phase behavior shown in Figure 58 is typical for anionic surfactants and plays an important role in the efficiency of soil removal and in the yield value and phase stability of liquid detergent formulations.

Figure 58. Phase diagram for C_{14} fatty alcohol sulfate in water at pH 11.5. L1 is the micellar phase, Hex LC the hexagonal, and Lam LC the lamellar phase [81]

Figure 59. Viscosity and the yield value for two fatty alcohol sulfates with different alkyl chain length [81]

2.5.4. Softeners

The softening effect of cationic substances adsorbing on the textile surface is a well-known process. Mostly the substances responsible for the effect are quaternary ammonium compounds like ditallow alkyl dimethyl ammonium chloride or *N*-methyl-*N*,*N*,*N*-triethanolamine ditallow ester. Because of their positive charge they are adsorbed selectively on the negatively charged textile surface. The adsorbed amounts of quaternary compounds are very different for the various textile types. On cotton and wool the adsorption is highest, whereas it decreases for the synthetic fibers polyamide, polyacrylonitrile, and polyester, as shown in Figure 60 [118]. Because of interactions with the anionic surfactants of the detergent formulation the quaternary cationic compounds cannot be added directly to the detergent formulation. Due to the insufficient biodegradability of compounds like ditallow alkyl dimethyl ammonium chloride, they were changed into the more readily biodegradable ester quaternary ammonium compounds mentioned above. The adsorption behavior, however, remains the same for both compound classes.

Figure 60. Adsorption of ditallow alkyl dimethyl ammonium chloride on different textiles [118]

2.6. Concluding Remarks

To simplify a physicochemical approach to the washing process, it has been necessary to treat separately each of the several phenomena involved and to isolate them from one another. In any real washing process, the various mechanisms are all at work more or less simultaneously. Thus, these mechanisms affect one another in a mutually supportive and additive way. Investigations on the physical chemistry of washing have made possible a rather thorough understanding of the process. Despite the complexity of the washing phenomenon and the continued presence of certain unanswered questions, increasing knowledge of physicochemical correlations has exerted a major influence on product development.

3. Detergent Ingredients

Detergents for household and institutional use are complex formulations containing up to more than 25 different ingredients. These can be categorized into the following major groups:

Surfactants
Builders
Bleaching agents
Auxiliary agents (additives)

Each individual component of a detergent has its own very specific functions in the washing process. To some extent they have synergistic effects on one another. In addition to the above ingredients, certain additives are made necessary for production reasons, whereas other materials may be added to improve product appearance.

3.1. Surfactants

Surfactants constitute the most important group of detergent components, and they are present in all types of detergents. Generally, surfactants are water-soluble surface-active agents comprised of a hydrophobic portion (usually a long alkyl chain) attached to hydrophilic or solubility-enhancing functional groups.

A surfactant can be grouped in one of four classes, depending on what charge is present in the chain-carrying portion of the molecule after dissociation in aqueous solution:

Anionic surfactants
Nonionic surfactants
Cationic surfactants
Amphoteric surfactants

Table 10 [125] provides an overview of these classes.

In general, both adsorption and detergency performance increase with increasing chain length. For example, ionic surfactants bearing *n*-alkyl groups show a linear relationship between the number of carbon atoms in the surfactant molecule and the logarithm of the amount of surfactant adsorbed on activated carbon or kaolin clay.

Figure 61. Decrease in adsorbed amount Q at equilibrium with increased branching of the hydrophobic residue [126] Adsorbent: activated carbon M; amount of adsorbent: 0.050 g; particle diameter: 0.084 cm; surfactant:

surfactant concentration: 1×10^{-4} mol/L; temperature: 25 °C

The structure of the hydrophobic residue also has a significant effect on surfactant properties. Surfactants with little branching in their alkyl chains generally show a good cleaning effect but relatively poor wetting characteristics, whereas more highly branched surfactants are good wetting agents but have unsatisfactory detergency performance. For compounds containing an equal number of carbon atoms in their hydrophobic chains, wetting power increases markedly as the hydrophilic groups move to the center of the chain or as branching increases. Simultaneously a decrease in adsorption and detergency performance occurs (Figs. 61 and 62).

Figure 62. Decrease in soil removal S from soiled cotton as a function of increased branching in the hydrophobic residue [126]

Surfactant:

temperature: 90 °C; bath ratio: 1 : 12.5; water hardness: 16 °d (285 ppm); surfactant concentration: 2.91×10^{-3} mol/L

The changes with respect to adsorption, wetting, and detergency performance that result from varying the degree of branching are far more significant for ionic surfactants than for nonionic surfactants. In the case of anionic surfactants, losses in detergency performance caused by increased branching can be compensated for to some extent, provided the overall number of carbon atoms is increased appropriately.

Table 10. Surfactants of various ionic nature [125]

Surfactant	Formula	Electrolytic dissociation	Ionic nature
Alkyl poly(ethylene glycol) ethers	$RO-(CH_2-CH_2-O)_nH$	no	nonionic
Alkylsulfonates	$R-SO_3^-\ Na^+$	yes	anionic
Dialkyldimethylammonium chlorides	$\left[H_3C-N^+(R)_2-CH_3\right] Cl^-$	yes	cationic
Betaines	$R-N^+(CH_3)_2-CH_2-C(=O)O^-$		amphoteric

Household washing of textiles normally poses few situations requiring extraordinary wetting power. If problems arise, they can usually be overcome by increasing the wash time or the amount of detergent used. Most important is the effectiveness of the rolling-up process. Optical microscopy has revealed that oily and greasy soil tends to reside in more or less evenly distributed layers on the surface of fibers. These layers are gradually constricted by the action of a surfactant and its associated spreading pressure, with the layers ultimately being reduced to drops resting loosely on the fibers, which are then easily detached. Thus, oily residue as a fiber wetting agent is replaced by aqueous wash solution.

The number of types of surfactants suitable for use in laundry products has increased considerably in the past 50 years. The principal criteria for judging surfactant suitability apart from performance are toxicological and ecological characteristics. Cationic and nonionic surfactants have come to play an increasingly important role along with their anionic counterparts (cf. Table 11). Despite the wide choice of possibilities, however, only few surfactants account for the major share of the market, partly as a result of economic factors [120], [127].

Anionic surfactants are the most common ingredients in detergents designed for laundry, dishwashing, and general cleansing. Nonionic surfactants such as alcohol ethoxylates have acquired great importance during the last decades. Cationic surfactant use is largely restricted to fabric softeners because of the fundamental incompatibility of these materials with anionic surfactants and their poor cleaning efficiency. Amphoteric surfactants still lack a significant place in the market. Around the world a remarkable variability in the types of surfactants employed in products for similar purposes can be seen. The reasons are to be found in the variations in the kinds of fabric encountered worldwide, the diversity in washing machine technology, and different regional habits for fabric use and care (Fig. 63).

Wash technology has been the subject of major changes and developments during the past 50 years. The textile market has also changed, with synthetic fibers playing an increasingly large role. The wide variety of textile fibers and fiber blends and their differing characteristics have forced manufacturers to devise surfactants with a broad performance range. No single surfactant is capable of fulfilling all demands in an optimal way; consequently, the trend has been increasingly toward using surfactant blends, in which the characteristics of each component are intended to supplement those of the others. The widening scope of the demand for surfactants used in detergents not only relates to performance, but encompasses toxicological, ecological, and economic considerations as well. Surfactants suitable for detergent use are expected to demonstrate the following characteristics [129, 130]:

Specific adsorption
Excellent soil removal
Low sensitivity to water hardness
Good dispersion properties
Good soil antiredeposition capability
High solubility
Sufficient wetting power
Desirable foam characteristics
Neutral odor
Low intrinsic color
Sufficient storage stability
Good handling characteristics
Low toxicity to humans
Favorable environmental behavior
Assured raw material supply
Competitive costs

3.1.1. Anionic Surfactants

Most detergents contain larger amounts of anionic surfactants than nonionic surfactants. The following discussion deals with anionic surfactants that are in widespread use and/or have favorable characteristics. Anionic surfactants and their manufacturing processes are amply described in the literature [273].

Soap. Soap is no longer as important in many parts of the world as it was before the existence of mass-produced synthetic surfactants. Although soap powders for washing once contained as much as 40 % soap as their sole surfactant, powder detergents have since the 1950s been formulated with mixtures of far more effective surfactants in considerably smaller proportion. A further reason for the decreasing use

Table 11. Key surfactants

Structure		Chemical name	Acronym
Anionic surfactants			
	$R = C_{10-16}$	soaps

Figure 63. 1995 Global use pattern of major surfactants [128]

of soap in laundry detergents is its sensitivity to water hardness, manifested through inactivation due to the formation of lime soap, which tends to accumulate on fabrics and washing machine parts. Such accumulation reduces the absorbency of fabrics and their permeability to air, and eventually through "aging" causes laundry to become discolored and to develop malodors.

The primary function that remains for soap currently is as a foam regulator in laundry detergents in Europe. Nonetheless, soap has remained worldwide the largest surfactant by volume. It is still the surfactant of choice in many countries with low gross national product (cf. Chap. 9 and cf. Section 3.4.3).

Alkylbenzenesulfonates (LAS and TPS). Until the mid-1960s, this largest class of synthetic surfactants was most prominently represented by tetrapropylenebenzenesulfonate (TPS):

In the 1950s TPS had largely replaced soap as an active ingredient in laundry detergents in Europe, the USA, and Japan. It was later found, however, that the branched side-chain present in TPS prevents the compound from undergoing sufficient biodegradation. Thus, means were developed to replace it by more readily biodegradable straight-chain homologues. Since that time, favorable economic circumstances and good performance characteristics have permitted straight-chain or linear alkylbenzenesulfonates (LAS) to take the lead among laundry detergent surfactants in Europe, the Americas, and Asia. Nevertheless, a few countries remain in which TPS continues to be used in detergents (see Section 10.3.1). The large-scale manufacturing methods for LAS have been reviewed [137].

$n + m = 7–10$ LAS

Apart from their very good detergency performance, LAS have interesting foaming characteristics, which are of great significance to their use in detergents. Their foaming ability is high, and the foam that is produced is readily stabilized by foam stabilizers, an important factor in many parts of the world. At the same time, however, LAS can be controlled easily by foam regulators, and this is significant with respect to detergents for the European market, where horizontal-axis drum-type washing machines are common.

As a result of their high solubility, LAS are also frequently employed in formulations for liquid detergents. However, LAS are sensitive to water hardness: the detergency performance of LAS diminishes as the hardness of the water increases. The relationship between water hardness and performance for a series of surfactants in the absence of builders or sequestrants is well demonstrated by soil removal from wool, as illustrated in Figure 64.

Figure 64. Detergency performance on wool by various surfactants as a function of water hardness [131]
Time: 15 min; temperature: 30 °C; bath ratio: 1 : 50; concentration: 0.5 g/L surfactant + 1.5 g/L sodium sulfate
a) Nonylphenol 9 EO; b) C_{12-14} Alcohol 2 EO sulfates; c) C_{15-18} α-Olefinsulfonates; d) C_{16-18} α-Sulfo fatty acid esters; e) C_{12-18} Alcohol sulfates; f) C_{10-13} Alkylbenzenesulfonates; g) C_{13-18} Alkanesulfonates

The decline in detergency performance with increasing water hardness is most dramatic with soap. Sensitivity to water hardness largely disappears in built formulations (zeolite A, triphosphate, soda ash, etc.) because of sequestration,

binding, or ion exchange of the water hardness ions (cf. Chap. 2, Fig. 17). Figure 65 illustrates wool wash performance for various readily accessible anionic surfactants in the absence of complexing agents, plotted as a function of surfactant concentration. It can be seen that products with a lower sensitivity to hardness display only a slight advantage.

Figure 65. Detergency performance on wool of various synthetic anionic surfactants as a function of concentration [129]
Product: 25 % surfactant + 75 % sodium sulfate; temperature: 30 °C; wash time: 15 min; bath ratio: 1 : 30; water hardness: 16 °d (285 ppm $CaCO_3$)
a) C_{12-14} Alcohol 2 EO sulfates; b) C_{15-18} α-Olefinsulfonates; c) C_{16-18} α-Sulfo fatty acid esters; d) C_{13-18} Alkanesulfonates; e) Alkylbenzenesulfonates

Secondary Alkanesulfonates (SAS).

$R^1 + R^2 = C_{11-17}$

Sodium alkanesulfonates (SAS) have been known as commercial surfactants since the 1940s. Their large-scale production began in the late 1960s. Sodium alkanesulfonates are still valued as specialty anionic surfactants for consumer products. Their 1998 demand amounted to only 60×10^3 t. SAS feature high solubility, fast wetting properties, chemical stability to alkali, acids, and strong oxidants including chlorine. Sodium alkanesulfonates are produced by photochemical sulfoxidation or sulfochlorination of suitable C_{12}–C_{18} paraffin cuts. Manufacturing, properties, applications, and characteristics of SAS have been reviewed [132 – 135]. Sodium alkanesulfonates are the compounds that closely resemble LAS in terms of solubility, solubilizing properties, wetting power and other detergency properties. Therefore, SAS can largely be substituted for LAS in most formulations.

Alkanesulfonates are completely insensitive to hydrolysis even at extreme pH values, a result of the presence of the stable carbon–sulfur bond.

The water hardness sensitivity and foaming characteristics of SAS largely resemble those of LAS, as discussed above.

α-Olefinsulfonates (AOS).

R^1–CH_2–CH=CH–$(CH_2)_n$–SO_3Na Alkenesulfonates

Hydroxyalkanesulfonates

$R^1 = C_8$–C_{12} $n = 1, 2, 3$
$R^2 = C_7$–C_{13} $m = 1, 2, 3$

α-Olefinsulfonates (AOS) are produced commercially starting from α-olefins. Alkaline hydrolysis of the sultone intermediate results in ca. 60–65 % alkenesulfonates and ca. 35–40 % hydroxyalkanesulfonates. Because of the use of olefinic precursors, these mixtures are customarily called α-olefinsulfonates.

In contrast to LAS and SAS, AOS show little sensitivity to water hardness (cf. Fig. 64). This apparent advantage is only of significance in a few very special applications, however. Depending on chain length, AOS may cause foaming problems in drum-type washing machines, which requires the addition of special foam regulators. Since this problem does not arise with washing machines of the type used in Japan, AOS have long been an important component of some Japanese detergents.

In addition to α-olefinsulfonates, sulfonates prepared from olefins with internal or central double bonds and from vinylidene olefins also exist. These types of olefinsulfonates are unsuitable for detergent use, however, because of their poor performance characteristics. In Figure 66, a C_{15-18} α-olefinsulfonate is compared with a C_{15-18} internal olefinsulfonate, the inferior performance of which is clearly apparent. The reason for the difference is the fact that AOS have their hydrophilic group in a terminal position, whereas with the internal olefinsulfonates, additional isomers can arise in which hydrophilic groups are distributed throughout the entire hydrophobic chain. This has the same consequences as branching (cf. Section 3.1). However, olefinsulfonates prepared from internal olefins generally show very good textile wetting characteristics.

Figure 66. Performance of various olefinsulfonates [136] Water hardness: 16 °d (285 ppm $CaCO_3$); wash time: 30 min; wash temperature: 60 °C
a) 0.75 g/L C_{15-18} Internal olefinsulfonates + 2.0 g/L sodium triphosphate; b) 0.75 g/L C_{15-18} α-Olefinsulfonates + 2.0 g/L sodium triphosphate

α-Sulfo Fatty Acid Esters (MES)

α-Sulfo fatty acid methyl esters

Another class of anionic surfactants is the α-sulfo fatty acid esters, particularly the methyl derivatives. This group of surfactants is also called methyl ester sulfonates (MES). Methyl ester sulfonates are derived from a variety of methyl ester feedstocks from renewable resources, such as coconut, palm kernel, palm stearin, beef tallow, lard, and soy. Good detergency performance is attained with products having rather long hydrophobic residues (e.g., palmitic and stearic acid derivatives) [137]. The sensitivity of MES to water hardness is small relative to that of LAS and SAS, more closely resembling that of AOS. One of the interesting detergency properties of α-sulfo fatty acid methyl esters is their exceptional dispersion power with respect to lime soap.

Special attention is to be paid to the manufacturing of finished laundry products based on MES. Insufficient storage stability of MES has so far impeded their large-scale use in detergents; they have only been used in a few Japanese detergents [138].

Alkyl Sulfates (AS).

Alkyl sulfates (AS), also known as alcohol sulfates, achieved prominence as early as the 1930s in detergents for delicate fabrics in Germany and the USA and as components of textile auxiliaries. Their availability resulted from the development by Schrauth to produce primary fatty alcohols by high-pressure hydrogenation of fatty acids and their methyl esters. Alkyl sulfates are produced either from natural fatty alcohols derived from palm oil, palm kernel oil, or coconut oil, or from oxo alcohols, i.e., of petrochemical origin [127]. They are characterized by desirable detergency properties, and have found increasing application not only in specialty products, but also in heavy-duty detergents, especially in those concentrated products produced by nontower technology (cf. Section 6.2.3).

Alcohol sulfates derived from natural, renewable feedstocks have been playing a steadily increasing role as surfactants in laundry detergents since the 1980s. They have found increasing application at the expense of LAS [119, 127, 139 – 142].

Alkyl Ether Sulfates (AESs).

Alkyl ether sulfates

1. $R^1 = H, R^2 = C_{10-12}$ — Fatty alcohol ether sulfates
2. $R^1 + R^2 = C_{11-13}$ — Oxo alcohol ether sulfates
   $R^1 = H, C_1, C_2 \ldots$

$n = 1–2$

Alkyl ether sulfates (AES), also known as alcohol ether sulfates, are obtained by ethoxylation and subsequent sulfation of alcohols derived from natural feedstocks or of synthetic alcohols. They exhibit the following unique characteristics relative to alkyl sulfates:

Low sensitivity to water hardness (cf. Fig. 64)
High solubility
Good storage stability at low temperature in liquid formulations

Commercial AESs consist of alkyl ether sulfates and alkyl sulfates as the main components. Unsulfated alcohols, alcohol ethoxylates, inorganic salts, and poly(ethylene oxide) sulfates are contained as byproducts [127]. Manufacturing, properties, and analysis of AES have been reviewed [143].

Alcohol ether sulfates that are least sensitive to water hardness, e.g., sodium C_{12-14} *n*-alkyl diethylene glycol ether sulfates, actually demonstrate increased detergency performance (e.g., on wool) as the hardness increases. This is a result of the positive electrolyte effects attributable to calcium/magnesium ions. Addition of sodium sulfate produces a slight improvement of detergency performance only in regions of low water hardness. However, detergency performance declines in the presence of sodium triphosphate due to calcium/magnesium sequestration (cf. Fig. 67).

Binding of alkaline earth ions can occur not only through complexation, but also as a result of ion exchange. Calcium ions can be exchanged particularly effectively and with favorable kinetics by using zeolite A. The properties discussed above in the context of calcium sequestration can be equally well described in terms of ion exchange.

From the foregoing, it follows that if one were to undertake the development of, for example, a wool detergent, an important consideration would be the careful choice of supplemental salts; i.e., the presence of complexing agents or ion exchangers is not always advantageous in a detergent formulation containing surfactants if these are insensitive to water hardness. On the other hand, a surfactant that is sensitive to water hardness is not necessarily inferior, provided it is combined with the proper complexing agents or ion exchangers. The situation can be somewhat more complicated, however, if a detergent has to be developed for fibers whose nature requires the presence of complexing agents for proper washing.

Figure 67. Soil removal *S* from wool as a function of water hardness at 30 °C with 0.5 g/L sodium C_{12-14} *n*-alkyl diethylene glycol ether sulfates containing no added electrolyte

a) with 1.5 g/L sodium sulfate
b) and with 1.5 g/L sodium triphosphate
c) [46]

Alkyl ether sulfates are very intensively foaming compounds that are well suited for usein high-foam detergents for vertical-axis washing machines, but are less directly applicable to detergents for horizontal-axis drum-type machines. Because of their specific properties, alkyl ether sulfates are preferred constituents of detergents for delicate or wool washables, as well as foam baths, hair shampoos, and manual dishwashing agents. The optimal carbon chain length has been established to be C_{12-14} with ca. 2 mol of ethylene oxide.

Alcohol ether sulfates have achieved some importance in the U.S. and Japanese markets.

This is because their critical micelle concentration is considerably lower than that for LAS, resulting in very satisfactory washing power even at the low detergent concentrations typical in these countries. In Europe, the use of alcohol ether sulfates has so far been largely restricted to specialty detergents.

Alkyl ether sulfates were formerly prepared exclusively by ethoxylation and sulfation of native fatty alcohols. For a long time, synthetic alcohols have also been used, particularly the partially branched oxo alcohols. Oxo alcohol ether sulfates have good wetting properties comparable to those of straight-chain native fatty alcohol ether sulfates, whereas their detergency performance is inferior to the latter [144].

3.1.2. Nonionic Surfactants

3.1.2.1. Alcohol Ethoxylates (AE)

Nonionic surfactants of the alcohol ethoxylate (AE) type do not dissociate in aqueous solution. Some of their properties can be singled out for special attention:

The absence of electrostatic interactions
Behavior with respect to electrolytes
The possibility of favorable adjustment of hydrophilic–lipophilic balance values (HLB)
Anomalous solubility in water

Adsorption phenomena involving nonionic surfactants can be explained on the basis of hydrophobic interactions, in some cases coupled with steric effects. Electrolytes have no direct influence on adsorption with nonionic surfactants. Nonionic surfactant detergency performance is adversely affected by the presence of polyvalent cations. These cations cause reduced negative ζ-potentials of fiber surface and soil, leading to reduced repulsion and correspondingly poor soil removal.

An important advantage of nonionic surfactants of the alcohol ethoxylate type is the fact that a proper balance (HLB) can be easily achieved between the hydrophobic and hydrophilic portions of the nonionic surfactants. For example, the hydrophilic portion of the molecule can be extended gradually by stepwise addition of ethylene oxide moieties. This leads to a stepwise increase in hydration and corresponding successive increase in solubility. On the other hand, with ionic surfactants, the presence of even one ionic group makes such a strong contribution to hydrophilic character that the introduction of further ionic groups totally eliminates the possibility of any equilibrium relationship with respect to the hydrophobic portion. The result is a rapid deterioration of typical surfactant characteristics. For a surfactant bearing two strong ionic hydrophilic groups to show washing activity, a considerably longer alkyl chain ($> C_{20}$) would be necessary.

Nonionic surfactants with a given hydrophobic residue can be adjusted to have optimal properties for various substrates with respect to adsorption and detergency performance simply by changing the degree of ethoxylation. Performance shows an initial increase with an increasing degree of ethoxylation, but a point is then reached after which it declines markedly (Fig. 68). Textile wetting power often decreases only at very high degrees of ethoxylation, whereas the wetting power for hard hydrophobic surfaces continues to climb as the number of ethoxy groups increases.

Figure 68. Detergency performance on wool and cloud point of C_{13-15} oxo alcohols as a function of degree of ethoxylation [129]
a) Detergency performance on wool (temperature: 30 °C; water hardness: 16 °d (285 ppm $CaCO_3$); bath ratio: 1 : 30; time: 15 min; concentration: 0.75 g/L surfactant +2.25 g/L sodium sulfate); b) Cloud point (surfactant concentration 10 g/L)

Alcohol ethoxylates show a solubility anomaly: when they are heated in aqueous solution, suddenly turbidity appears, usually at a relatively precise temperature. This is caused by a separation of the alcohol ethoxylate solution into two phases, one with a high water content and one with a low water content. The

corresponding characteristic temperature for a given surfactant is known as its cloud point. The cloud point moves to a higher temperature as the number of ethoxy groups increases. If the cloud point is not greatly exceeded, then the largely aqueous phases and largely surfactant phases form an emulsion. For a given surfactant, adsorption (hence, detergency performance) decreases when the cloud point is surpassed to a significant extent. The main reason for this behavior is the reduced solubility of the alcohol ethoxylates, which are then expelled from the aqueous phase. Nevertheless, nonionic surfactants with a cloud point somewhat below the application temperature commonly show better performance than those whose cloud point is higher (Fig. 68). Thus, the wash temperature is a significant factor in determining an optimal degree of ethoxylation (Table 12). The table shows that the best detergency performance is obtained when the temperature is maintained near the cloud point.

The cloud point can be greatly reduced by addition of several grams of electrolytes per liter, depending on the surfactant. However, everything said in this section is strictly applicable only to systems comprised of pure nonionic surfactants. For binary mixtures of nonionic and ionic surfactants, it is important to recognize that even a small amount of ionic surfactant can cause the cloud point to rise more or less dramatically.

The share of nonionic surfactants in overall surfactant production and use has been increasing since the 1970s. The major contributors to this increase have been fatty alcohol, oxo alcohol, and secondary alcohol ethoxylates, all of which are obtained by reaction of the corresponding alcohols with ethylene oxide. By varying the carbon chain length and the degree of ethoxylation, these nonionic surfactants can be tailor-made with respect to the washing temperature. For these reasons, the increased use of nonionic surfactants has been partly concomitant with the trend to wash at lower temperature and with changes in the production shares of different fibers [119, 145].

The reasons for the increased use of nonionic surfactants are found in their favorable detergency properties, particularly with respect to synthetics, and the decrease in wash temperatures observed since the 1970s.

Favorable detergency properties of nonionic surfactants derive largely from the following factors:

Low critical micelle concentration (c_M)
Very good detergency performance
Excellent soil antiredeposition characteristics with synthetic fibers

The low c_M values of nonionic surfactants indicate that they display high detergency performance even at relatively low concentrations. Table 13 provides data illustrating the low c_M of these compounds relative to that of anionic surfactants.

Table 13. Critical micelle concentration c_M of various surfactants [131]

Surfactant	c_M, g/L
LAS (C_{10-13} alkyl)	0.65
C_{12-17} Alkanesulfonates	0.35
C_{15-18} α-Olefinsulfonates	0.30
C_{12-14} Fatty alcohol 2 EO sulfates	0.30
Nonylphenol 9 EO	0.049
Oleyl/cetyl alcohol 10 EO *	0.035

* Iodine number 45.

3.1.2.2. Alkylphenol Ethoxylates (APE)

Alkylphenol ethoxylates (APE), are based on *p*-octyl-, nonyl-, and dodecylphenol poly(ethylene glycol) ethers. They achieved early success due to their exceptional detergency properties, particularly their oil and fat removal characteristics.

$R = C_{8-12}$ $n = 5–10$

The usage of APE has greatly declined, however, especially in Europe since 1986, due to their environmental characteristics, particularly the extent of their biodegradability and the fish toxicity of certain metabolites resulting from partial biodegradation (see Chap. 10).

3.1.2.3. Fatty Acid Alkanolamides (FAA)

Fatty acid alkanolamides are ethanolamides of fatty acids with the following structure:

Table 12. Detergency performance (in % remission) of alcohol ethoxylates with comparable cloud points [131]

Surfactant *	Cloud point, °C	Cotton 60 °C	Cotton 90 °C	Permanent-press cotton 60 °C	Permanent-press cotton 90 °C	Polyester/cotton 60 °C	Polyester/cotton 90 °C
C_{11-15} *sec*-Alcohol 9 EO	59	71	53	69	55	65	48
C_{9-11} Oxo alcohol 7 EO	61	57	44	66	52	53	43
Oleyl/cetyl alcohol 10 EO **	89	60	68	70	72	57	67
C_{13-15} Oxo alcohol 11 EO	88	54	69	67	69	53	58

* Surfactant concentration: 0.75 g/L; water hardness: 16 °d (285 ppm); wash time: 30 min.
** Iodine number 45.

$R = C_{11-17}$ $n = 1, 2$ $m = 0, 1$

Fatty acid alkanolamides find only little application in laundry detergents. Their most important feature is foam boosting, i.e., adding desired stability to the foam produced by detergents prone to heavy foaming. This property is not desirable for horizontal-axis drum-type washing machines employed, e.g., in Europe. Nevertheless, small amounts of FAA as cosurfactants are capable of enhancing the soil removal properties of the classical detergent components at low washing temperatures.

3.1.2.4. Alkylamine Oxides

The alkylamine oxides are produced by oxidation of tertiary amines with hydrogen peroxide. They are compounds that exhibit cationic behavior in acidic conditions (pH < 3), but they behave as nonionic surfactants under neutral or alkaline conditions. For this reason they are included in the nonionic surfactant category.

$R = C_{12-16}$

Compounds in this class have been known since 1934 and were described as detergent components in a patent issued to IG-Farbenfabriken. Combinations of alkylbenzenesulfonates and specific amine oxides are reputed to be especially gentle to the skin. Despite good detergency properties, however, they are rarely included in laundry detergent fromulations. The reasons for this include high cost, low thermal stability, and high foam stability.

3.1.2.5. *N*-Methylglucamides (NMG)

N-Methylglucamides are a new type of nonionic surfactants, that has been introduced in detergents in the 1990s. *N*-Methylglucamides derive their hydrophilic character from the hydroxyl groups of sugar or starch glucose moieties. These surfactants are obtained by reacting sugars with methylamine and subsequent acylation with fatty acid. They have increasingly been used as co-surfactants in powder and liquid detergent formulations.

3.1.2.6. Alkylpolyglycosides (APG)

Alkylpolyglycosides are produced by the dehydration–condensation reaction of alcohols with glucose. Alkylpolyglycosides have distinct lathering characteristics, especially in combination with anionic surfactants. Due to their good foaming properties APG are predominantly used in dishwashing detergents, liquid detergents, and specialty detergents for fine fabrics.

Excellent skin compatibility is one of the outstanding characteristics of alkylpolyglycosides. Many APG compounds with special properties can be synthesized by varying the alkyl chain length and the degree of glucose polymerization [146]. Since APG are completely based on natural resources, they biodegrade easily and rapidly to carbon dioxide and water only.

3.1.3. Cationic Surfactants

Long-chain cationic surfactants such as distearyldimethylammonium chloride (DSDMAC) exhibit extraordinarily high sorption power with respect to a wide variety of surfaces [147, 148, 151, 152]. They are very strongly absorbed to the surface of natural fibers, such as cotton, wool, and linen. Adsorption on synthetic fibers is much less pronounced. Figure 69 shows this behavior for several textile fibers. Adsorption rises steeply at low surfactant concentrations, followed by rapid saturation as the concentration increases. This behavior suggests complete coverage of boundary surfaces.

At the same time, cationic surfactants display behavior opposite to that of anionic surfactants as regards charge relationships on solids. Since the surfactant molecules bear a positive charge, their adsorption reduces the negative ζ-potential of solids present in aqueous solution, thereby reducing mutual repulsions, including that between soil and fibers. Use of higher surfactant concentrations causes charge reversal; thus, solid particles become positively charged, resulting again in repulsion. Soil removal can be achieved if adequate amounts of cationic surfactants are present and if their alkyl chains are somewhat longer than those of comparable anionic surfactants. This fact has little practical significance, however, since the subsequent rinse and dilution processes cause charge reversal in the direction of negative ζ-potentials, whereby a large fraction of the previously removed soil is once more attracted to the fibers. Therefore, cationic surfactants are employed only for the purpose of achieving certain special effects, which include applications in rinse-cycle fabric softeners, antistatic agents, and microbicides.

Figure 69. Adsorption isotherms of distearyldimethylammonium chloride (DSDMAC) on wool (a), cotton (b), and polyacrylonitrile (c) [147]
Temperature: 23 °C; time: 20 min; bath ratio: 1 : 10

Mixtures made up of equivalent amounts of anionic surfactant and cationic surfactant remain virtually unadsorbed on surfaces and thus display no washing effect. Reactions between anionic and cationic surfactants produce neutral salts with extremely low water solubility. Regarding the washing process, these salts behave like an additional load of greasy soil. On the other hand, addition of small amounts of certain specific cationic surfactants to an anionic surfactant — or even a nonionic surfactant — can enhance detergency performance.

Nonionic surfactants are more tolerant of the presence of cationic surfactants than anionic surfactants. Mixtures of the two are sometimes used in specialty detergents intended to have a wash-cycle fabric-softening effect. In such cases, it must be taken into account that adsorption of the cationic surfactant can be greatly reduced by the

presence of the nonionic surfactant, depending on the concentration of the latter, a phenomenon that can have a negative influence on the fabric-softening characteristics (Fig. 70).

Figure 70. Adsorption isotherms of distearyldimethylammonium chloride (DSDMAC) on cotton as a function of the alkyl polyglycol ether : DSDMAC ratio at equilibrium [147] Temperature: 23 °C; time: 20 min; bath ratio: 1 : 10

Dialkyldimethylammonium Chlorides. The first surfactant developed in this category was distearyldimethylammonium chloride (DSDMAC), introduced in 1949 as a fabric softener for cotton diapers and presented to the U.S. market a year later as a laundry rinse-cycle fabric softener.

R = C_{16-18}

Only in the mid-1960s did these surfactants begin to have a major impact as laundry aftertreatment aids on the U.S. and Western European markets (especially in the Federal Republic of Germany).

Imidazolinium salts such as 1-(alkylamidoethyl)-2-alkyl-3-methylimidazolinium methylsulfate have achieved a place as rinse-cycle softening agents, although not nearly as significant as that of DSDMAC.

R = C_{16-18}

Alkyldimethylbenzylammonium Chlorides. Compounds of the alkyldimethylbenzylammonium chloride type show only limited fabric softening character, but they have been used in laundry disinfecting agents as a result of their activity toward gram-positive and gram-negative bacteria.

R = C_{8-18}

The high adsorption capability of alkyldimethylbenzylammonium chloride also leads to applications as antistatic agents in laundry aftertreatment products.

Esterquats (EQ). In the new generation of fabric softeners that came up in the 1980s/1990s, DSDMAC has been largely replaced by esterquats, e.g., products with the following structures [149, 150]:

N-Methyl-*N*,*N*-bis[2-($C_{16/18}$-acyloxy)ethyl]-*N*-(2-hydroxyethyl)ammonium-methosulfate EQ (**E**ster**q**uat)

N,*N*,*N*-Trimethyl-*N*-[1,2-

di($C_{16/18}$-acyloxy)propyl] ammonium chloride DEQ (**Die**ster**q**uat)

Diethyl**e**ster **dim**ethyl **a**mmonium **c**hloride (DEEDMAC)R = Tallow fatty acid

Due to their ester bonds, which are potential breaking points, esterquats are readily biodegradable in contrast to DSDMAC, which is only poorly biodegradable (see Chap. 10). Esterquats have favorable ecotoxicological and toxicological properties. All available data proves that esterquats present no hazard for living organisms.

Esterquats have similar physicochemical and chemical properties as DSDMAC [149, 150]. It may be assumed that esterquats exhibit adsorption characteristics that are very similar to those of DSDMAC, as shown in Figure 69.

3.1.4. Amphoteric Surfactants

Compounds of the alkylbetaine or alkylsulfobetaine type possess both anionic and cationic groups in the same molecule even in aqueous solution. Despite what could be seen in some respects as excellent detergency properties, these surfactants are only rarely employed in laundry detergents, primarily for cost reasons. They are mainly applied in manual dishwashing products.

R = C_{12-18} Alkylbetaines

R = C_{12-18} Alkylsulfobetaines

3.2. Builders

Detergent builders play a central role in the course of the washing process [153]. Their function is largely that of supporting detergent action and of water softening, i.e., eliminating calcium and magnesium ions, which arise from the water and from soil.

The category of builders is predomintantly comprised of several types of materials: specific precipitating alkaline materials such as sodium carbonate and sodium silicate; complexing agents like sodium triphosphate or nitrilotriacetic acid (NTA); and ion exchangers, such as water-soluble polycarboxylic acids and zeolites (e.g., zeolite A).

Detergent builders must fulfill a number of criteria [46]:

1) Elimination of alkaline earth ions originating from
   - water
   - textiles
   - soil
2) Soil and stain removal
   - high specific detergency performance for particulate soil and fats
   - distinct detergency performance on specific textile fibers
   - enhancement of surfactant properties
   - dispersion of soil in detergent solutions
   - favorable influence on foam characteristics
3) Multiple wash cycle performance
   - good soil antiredeposition capability
   - prevention of lime deposits on textiles and washing machine parts
   - anticorrosion properties
4) Handling properties
   - sufficient chemical stability
   - no hygroscopicity
   - good color and odor qualities
   - compatibility with other detergent ingredients
   - good storage stability
   - assured raw material basis
5) Human toxicological safety assurance
6) Environmental properties
   - response to deactivation by biological degradation, adsorption, or other mechanisms

no adverse effects on the biological systems found in sewage plants and surface water
no uncontrolled accumulation
no heavy-metal ion remobilization
no eutrophication
no detrimental effects on drinking water quality

7) Cost effectiveness

3.2.1. Alkalies

Alkalies such as potash and soda ash have been used to enhance the washing effectiveness of water since antiquity. Their activity is based on the fact that soil and fibers become more negatively charged as the pH value increases, resulting in increased mutual repulsion. Alkali also precipitates ions that contribute to water hardness.

At the beginning of the 20th century, the principal ingredients (apart from soap) of all detergents were soda ash and silicate, which often made up nearly 50 % of the formulation of a powder detergent. These detergent ingredients were partly replaced during the 1930s by sodium monophosphate and diphosphate. All these builders removed water hardness by precipitation.

Figure 71. Comparison of soil removal (given as remission *R* in %) on permanent-press cotton at 0 °d and 90 °C for sodium triphosphate- and sodium carbonate-containing detergents, formulated on the basis of
a) 40 % Sodium triphosphate; b) 20 % Sodium triphosphate + 20 % sodium sulfate; c) 40 % Sodium carbonate

Modern builders no longer precipitate hardness; instead, water hardness is removed by complexation (sequestration) or ion exchange. Even commercial laundries using soft water have converted to detergents that are low in soda ash and contain the complexing agent sodium triphosphate. The latter has many valuable properties, among which are better detergency performance than soda ash (Fig. 71) [154].

3.2.2. Complexing Agents

Soda ash induces precipitation of calcium and magnesium salts from wash water. This can lead to formation of lime deposits on both laundry and washing machine parts. By contrast, sequestering agents form stable, water-soluble complexes with alkaline-earth ions, as well as with traces of heavy-metal present in water. Often the resulting complexes are chelates (Fig. 72). Sodium triphosphate forms a stable water-soluble complex with calcium when their stoichiometric ratio is 1 : 1 (Fig. 72). However, when a substoichiometric quantity of sodium triphosphate is present, the water-insoluble dicalcium triphosphate is formed, which precipitates on textile fibers and washing machine parts. Its precipitation can be impeded by adding small amounts of hydroxyethanediphosphonate and/or special polycarboxylates to the detergent formulation [167].

Temperature and complexing agent concentration are generally the decisive factors in successful elimination of polyvalent metal ions. Table 14 shows the calcium binding capacity of various sequestering agents as a function of temperature. Calcium binding capacity is here to be viewed as a quantitative measure of the stoichiometry of the resulting complexes. For most sequestering agents, this capacity decreases markedly with increasing temperature.

Regarding stability, the data presented show only that the stability constants (which are a function of the method of study employed, e.g., the dissolving power for freshly precipitated calcium carbonate) exceed a specific value that is dependent on the solubility of the calcium carbonate. Extremely high stability constants or stabilities, which would result in very low calcium ion concentrations, are not required; indeed, they are normally undesirable. It is important that

Table 14. Calcium binding capacity of selected sequestering agents [46]

Structure	Chemical name	Calcium binding capacity, mg CaO/g

	*O*-carboxymethyloxysuccinic acid	368	54

Figure 72. Metal complexes

those salts present to the greatest extent, such as calcium carbonate or others with even higher solubility products, be prevented from precipitating during the washing process. Less soluble calcium salts normally play a minor role.

Relative to other polyvalent ions, sequestration of alkaline earth ions is of primary concern because these ions are likely present in high concentration in tap water. Nevertheless, heavy-metal ions must also be eliminated because even in trace amounts their presence can have a negative effect on the washing process. For this reason, low concentrations of selective complexing agents are generally added as well, usually specific phosphonic acids, e.g., sodium hydroxyethanediphosphonate or sodium diethylenetriaminepentakis(methylenephosphonate).

If a sequestering agent is present in less than stoichiometric amounts relative to polyvalent metal ions, precipitation of carbonates and insoluble salts of the sequestering agent with the ions causing the water hardness usually results. Even with adequate amounts of sequestering agent, this effect is important because dilution during the rinse cycle can cause sequestrant concentration to drop below the necessary value, thereby permitting undesirable precipitates to form. These can build up on both fabric and washing machine components, leading eventually to serious accumulations. The problem can be particularly severe if conditions permit large crystals to form as a result of seed crystals located on fabric or machine components.

There are a number of compounds that even in substoichiometric amounts are capable of retarding, hindering, or otherwise interfering with precipitation of insoluble salts. In some cases their action induces salts to precipitate in amorphous form, thereby strongly reducing the tendency toward formation of crystals such as calcite, whose sharp edges can be damaging to fabrics. Sodium polycarboxylates and sodium hydroxyethanediphosphonate are frequently used additives in modern detergents, which strongly exhibit the latter property even at low concentrations; this is known as a *threshold effect* [167].

Despite the many desirable properties shown by sodium triphosphate in the washing process, its continued use has been the subject of an international debate between industry, governments, and water authorities in Europe, the USA, Japan, and other regions for many years. The problem has been that sodium triphosphate is a contributor to eutrophication of standing or slowly flowing surface waters; that is, it may lead to overfertilization, which in turn encourages extreme algal growth and adversely affects marine organisms. Recognition of the problem led to an intense worldwide search for suitable replacements in the 1960s and 1970s (see also Chap. 10). Developments have been concentrated not only on sequestering agents, but also on ion exchangers, since these are capable of binding polyvalent metal ions [155 – 157]. Most of the promising substitutes examined so far were organic compounds, primarily those derived from raw materials produced by the petrochemical industry. However, few of these substances were available in large quantity. The cost for commercial production on the necessary scale of $> 10^6$ t/a was in many cases prohibitive.

Apart from eliminating cations and achieving good soil and stain removal, other important factors in the washing process are dispersion of soil and prevention of soil redeposition (cf. Chap. 2). Because of the presence of distinct

localized charges, sequestering agents are readily adsorbed onto particulate soil. As a result, these compounds often act as effective dispersing agents for such soils.

Figures 73 and 74 show the relationship between dispersing agent concentration and sediment volume for two structurally different soil pigments where the sediment volume is understood as an indicator of the effectiveness of the dispersion process. Voluminous sediments are formed in the presence of poor dispersing agents; adsorption is insufficient to produce an adequate negative surface charge, and the result is coagulation. Figure 73 shows that the extent of dispersion, in this case of kaolin clay, depends on the specificity with which a sequestering agent is adsorbed. Virtually no effect is produced by sodium sulfate (a) and a nonionic surfactant (b). Anionic surfactants begin to show stabilization only at high concentrations that are rarely used in practice (f).

Figure 73. Sediment volume V_s of kaolin clay as a function of active ingredient concentration for water of hardness 16 °d (285 ppm $CaCO_3$) [46]
a) Sodium sulfate; b) C_{16-18} *n*-Alkyl decaglycol ethers; c) Hydroxyethyliminodiacetic acid, sodium salt; d) Nitrilotriacetic acid, sodium salt; e) Sodium triphosphate; f) Sodium *n*-dodecyl sulfate

With graphite, the results are exactly opposite to those observed with kaolin clay (Fig. 74). Sodium triphosphate alone shows no effect and is thus analogous to sodium sulfate (curves a and b), whereas sodium *n*-dodecyl sulfate has a very significant stabilizing effect. Because *n*-dodecyl sulfate is sensitive to water hardness, the dispersing effect increases with diminishing hardness; hence, the sediment volume decreases (both curves c: 16 and 0 °d). Although neither electrolytes nor sequestering agents alone are capable of stabilizing the particulate soil graphite, they are capable of exerting a positive influence, either indirectly through an electrolyte effect (curve d) or in hard water as a result of fixation of alkaline-earth ions (curve e). With sodium triphosphate, sequestration is accompanied not only by an electrolyte effect, but also by a pH effect. An increase in the hydroxide ion concentration and accompanying hydroxide ion adsorption causes increased electrostatic repulsion and, hence, better dispersion (reduced sediment volume). The indirect effect of sequestering agents on the dispersion of hydrophobic particulate soil applies also in principle to emulsification of water-insoluble greasy soil.

Figure 74. Sediment volume V_s of graphite as a function of active ingredient concentration [46]
a) Sodium sulfate; b) Sodium triphosphate; c) Sodium *n*-dodecyl sulfate; d) Sodium *n*-dodecyl sulfate + 1.5 g/L sodium sulfate; e) Sodium *n*-dodecyl sulfate + 1.5 g/L sodium triphosphate

A number of additional factors must be considered when selecting a sequestering agent for detergent use. Several important criteria have been listed in Section 3.2. The extent to which evaluation of a sequestering agent can vary depends on how the several criteria are weighted, as is apparent from Table 15.

3.2.3. Ion Exchangers

The disruptive effect of polyvalent metal ions can be reduced not only by the use of low molecular mass sequestering agents, but also by ion

Table 15. Evaluation of sequestering agents according to various criteria

Ingredient (as sodium salt)	Calcium sequestration	Detergency performance	Incrustation on fabrics and washing machines	Hygroscopicity
Sodium diphosphate	low	very good	very heavy	insignificant
Sodium triphosphate	adequate	very good	little	insignificant
1-Hydroxyethane-1,1-diphosphonic acid	very high	very good	very little	hygroscopic
Nitrilotrimethylenephosphonic acid	high	good	little	very hygroscopic
Nitrilotriacetic acid	high	very good	very little	hygroscopic
N-(2-hydroxyethyl)iminodiacetic acid	less adequate	good		very hygroscopic
Ethylenediaminetetraacetic acid	high	good	very little	very hygroscopic
1,2,3,4-Cyclopentanetetracarboxylic acid	high	fair	little	hygroscopic
Citric acid	low	fairly low	little	insignificant
O-Carboxymethyltartronic acid	high	good	little	hygroscopic
O-Carboxymethyloxysuccinic acid	less adequate	fair		hygroscopic

exchangers [156]. Table 16 shows that ion exchangers generally have a high binding capacity for calcium but that this usually decreases with increasing temperature.

In the early years the idea of introducing water-insoluble substances into detergents had never been seriously investigated. This was primarily because the known materials lacked sufficient calcium binding ability, were available only in forms with unsuitable particle structure, and were deemed impractical for economic reasons. Success was first achieved through research in the field of sodium aluminum silicates. Systematic investigation revealed that, among the many known types of sodium aluminum silicates, those with a regular crystalline form were appropriate for use in the washing process. One particular modification proved especially applicable and economically interesting: zeolite A [121 – 123, 159 – 163], manufactured under the registered name "Sasil" (**s**odium **a**luminum **sil**icate) [155 – 157]. The ion-exchange behavior of this particular water-insoluble crystalline sodium aluminum silicate (Table 16) depends on ionic size and on the state of hydration of the ions. In addition to Ca and Mg, exchange also takes place with, e.g., Pb, Cu, Ag, Cd, Zn, and Hg ions. The elimination of calcium ions — and to a lesser extent magnesium ions — is of greatest importance for the washing process, but ion exchange capacity for heavy metal ions is also important from an ecological standpoint.

Ion exchange is dependent not only on ionic size, but also on concentration, time, temperature, and pH value. Figure 75 shows the exchange kinetics as a function of concentration and time. Calcium ions are exchanged very rapidly. The process occurs somewhat more slowly with magnesium, although exchange becomes more rapid at higher temperature. These results can be explained by the larger hydration shell of magnesium ions that impedes exchange at low temperature but is largely destroyed at higher temperature.

Figure 75. Kinetics of calcium binding to zeolite A [164] Initial hardness: 30 °d (530 ppm $CaCO_3$); temperature: 25 °C

The fact that ion exchange occurs in a heterogeneous phase and that adsorption–desorption phenomena are absent means it is advantageous to employ combinations of sodium aluminum silicates with water-soluble sequestering agents. The latter have the ability to remove polyva-

Table 16. Calcium binding capacity of selected ion exchangers [158]

** Sodium salt.

lent cations, especially calcium and magnesium, from a solid surface, transport them through an aqueous medium, and then release them to the ion exchanger. This property is best described as a carrier effect consisting of the following steps (cf. also Fig. 22):

1) Sorption of the carrier onto the fiber–soil interface
2) Complexation of calcium and magnesium ions
3) Transfer from the solid fiber–soil interface through the wash liquor to the sodium aluminum silicate–water interface
4) Dissociation of the complex into carrier and calcium and magnesium ions
5) Ion exchange of calcium and magnesium ions for sodium ions in the sodium aluminum silicate crystalites
6) Renewed sorption of the carrier on the fiber–soil interface and further complexation with calcium and magnesium ions

If the properties of sodium triphosphate (a water-soluble sequestering agent) are compared with those of sodium aluminum silicate (zeolite A), a number of similarities become apparent, as do typical differences [156, 164]:

Characteristics of sodium triphosphate:
Characteristics of sodium triphosphate:

1) a) complex formation with polyvalent ions
   b) alkaline reaction
   c) specific adsorption on particulate soil and fibers
   d) specific electrostatic charging of particulate soil and fibers, dissolution of polyvalent ions from soil and fibers
   e) nonspecific electrolyte effect

Characteristics of sodium aluminum silicate:
2
a) binding capability for polyvalent ions through ion exchange
b) alkaline reaction
c) adsorption of molecularly dispersed substances
d) heterocoagulation with particulate soil
e) crystallization surface for poorly soluble compounds

The different properties of sodium triphosphate and sodium aluminum silicates can be explained on the basis of their differing solubilities and the divergent ways they eliminate ions contributing to water hardness. In the case of sodium triphosphate, calcium binding occurs by

chelation, whereas with sodium aluminum silicates, calcium binding is a result of ion exchange [164].

Ca^{2+} binding by chelation (sodium triphosphate):

Ca^{2+} binding by ion exchange (zeolite A):

Additional differences result from the exceptional adsorption capability of the triphosphate anion.

The binary builder system sodium triphosphate–zeolite A assures outstanding multiple wash cycle performance; that is, incrustations resulting from precipitation of calcium and magnesium phosphates are largely avoided. Replacement of sodium triphosphate by zeolite A in a detergent leads to some deterioration in removal of some soils and stains. By reoptimization of the detergent formulation with respect to surfactants, bleach system, enzymes, etc., this effect can be easily compensated for.

Alternative ion exchangers like certain water-soluble polycarboxylic acids have also achieved great importance for phosphate-free and low-phosphate detergents (see Section 3.2.4).

Zeolite A, as it is mass produced for use in detergents, appears as cubic crystals with rounded corners and edges. These crystalline particles show a tendency to form agglomerates [156, 160] (Fig. 76).

The average diameter of a zeolite A particle is ca. 4 µm. A diameter distribution curve obtained by differentiation of a residue summation curve (determined by using a Coulter counter) shows quite a sharp maximum at the corresponding abscissa value (Fig. 77).

Zeolite A is specially optimized for use in detergents. Its unique particle form, cubes with rounded corners, protects fibers against damage, and the tiny particles with their narrow range of particle sizes ensures that deposition on laundry is practically nonexistent [156].

3.2.4. Builder Combinations

Since the beginning of the 1980s, the ternary builder combination zeolite A–polycarboxylate–soda ash has been increasingly used in nonphosphate detergents all over the world [165]. Polycarboxylates — polyacrylate and poly(acrylate-*co*-maleinate) — have an outstanding function in this ternary builder system in that they effectively prevent lime and soil depositions on laundry and washing machines. The mechanism of action is based on the *threshold effect* (see Section 3.2.2) [166, 167]. Further ternary builder systems such as sodium triphosphate–sodium carbonate–sodium polycarboxylate are also frequently applied, of course only in those global regions where phosphate-built laundry detergents are common. The use of substoichiometric quantities of high molecular mass polymers or copolymers of acrylic and maleic acid in these formulations enables a reduction in the content of sodium triphosphate and its partial substitution by the more cost effective sodium carbonate. This is due to the ability of the polycarboxylates to retard or inhibit crystal growth of sparingly soluble salts, such as calcium phosphate and calcium carbonate. Increasing charge density of the polycarboxylic acid (i.e., maleate content in the copolymer) increases its sequestration capacity [167, 168].

Special crystalline and amorphous silicates, sodium carbonate–silicate compounds, and zeolite P are also used as alternatives to zeolite A. These alternatives are found in some European, U.S., and Japanese nonphosphate detergent formulations [169, 170]. Zeolite P was introduced as a builder in laundry detergents in 1994 [171, 172]. It has the chemical formula $Na_2O \cdot Al_2O_3 \cdot (2–5)\,SiO_2 \cdot x\,H_2O$ and is also known under the trade names zeolite MAP, Doucil A 24, and Wessalith NaP. Zeolite P has the advantage of substantially stronger calcium binding than zeolite A. Furthermore, zeolite P exhibits a superior uptake for nonionic surfactants due to is smaller average particle size and, hence, larger surface per unit weight than zeolite A [256, 288 – 290]. This property can be essential for special detergent manufacturing technologies.

Unlike zeolites, silicate-based builders are water-soluble and contribute to the alkalinity of the washing liquor. They are generally better compatible with sensitive bleach components such as percarbonate. Crystalline layered disilicate $Na_2Si_2O_5$ and sodium carbonate–sodium silicate are most suitable for use as detergent builders. They are commercially available under the tradenames SKS-6 and Nabion 15, respectively. Due to their superior efficiency in preventing buildup of lime deposits, they can replace zeolite A in nonphosphate detergents [169, 170, 282].

3.3. Bleaches

The term bleach can be taken in the widest sense to include the induction of any change toward a lighter shade in the color of an object. Physically, this implies an increase in the reflectance of visible light at the expense of absorption.

Bleaching effects can occur through mechanical, physical, and/or chemical means, specifi-

cally through change or removal of dyes and soil adhering to the bleached object. In the washing process, all of these processes occur in parallel, but to varying extents. The relative significance of each is determined in part by the nature of the soil and dyes present. Mechanical/physical mechanisms are effective primarily for the removal of particulate and greasy soil. Chemical bleaching is employed for the removal of colored nonwashable soils and stains adhering to fibers and is accomplished by oxidative or reductive decomposition of chromophoric systems. Only oxidative bleaches are used in laundry products to a great extent; many soils commonly encountered in everyday laundry contain compounds which, if bleached reductively, become colorless but may later return to their colored forms as a result of subsequent atmospheric oxidation. Nevertheless, this generalization does not rule out the use of special reductive bleaches (e.g., $NaHSO_3$, $Na_2S_2O_4$) to treat specific types of discoloration occurring in either household or institutional settings.

The extent of the bleaching effect that can be achieved is dependent on a number of factors, including the type of bleach, its oxidation potential and concentration, as well as the residence time in the washing or rinsing process, the wash temperature, the type of soil to be bleached, and the nature of the fabric.

Bleachable soils encountered in household and institutional laundry consist of a broad spectrum of diverse materials which are generally of vegetable origin and contain primarily polyphenolic compounds. These include the anthocyanin dyes derived from, e.g., cherries, blueberries, and currants, and curcuma dyes from curry and mustard. The brown tannins found in, e.g., fruit, tea, and wine stains arise from condensation of polyphenols with proteins. Other brown organic polymers include the humic acids present, for example, in coffee, tea, and cocoa. The green dye chlorophyll and the red betanin from beets are pyrrole derivatives, as are the urobilin and urobilinogen dyes derived from degradation of hemoglobin and discharged in urine. Carrot and tomato stains contain carotenoid dyes. Dyes of commercial origin such as those found in cosmetics, hair coloring agents, and ink are also important. Blood is also a bleachable soil, but its removal can sometimes present problems.

Two procedures have attained major importance in oxidative bleaching during the washing and rinsing processes: peroxide bleaching and hypochlorite bleaching. The relative extent of their application varies, depending heavily on laundering habits in the different global regions.

3.3.1. Bleach-Active Compounds

The dominant bleaches in Europe and many other regions of the world are of the *peroxide* variety. Hydrogen peroxide is converted by alkaline medium to the active intermediate hydrogen peroxide anion according to the following equation:

$$H_2O_2 + OH^- \rightleftharpoons H_2O + HO_2^-$$

The perhydroxyl anion oxidizes bleachable soils and stains. The usual sources of hydrogen peroxide are inorganic peroxides and peroxohydrates. The most frequently encountered source is sodium perborate (sodium peroxoborate tetrahydrate, $NaBO_3 \cdot 4\ H_2O$) [173], which in crystalline form contains the peroxodiborate anion:

Peroxodiborate is hydrolyzed in water to form hydrogen peroxide. Sodium perborate monohydrate and sodium percarbonate, which dissolve more quickly than perborate tetrahydrate, have been increasingly used either as separate color-safe bleach or in bleach-containing detergents at the expense of sodium perborate tetrahydrate. The monohydrate version has an improved storage stability as compared with the tetrahydrate version. Sodium perborate monohydrate is the preferred ingredient for laundry products in countries having high ambient temperatures because, contrary to perborate tetrahydrate, the monhydrate does not cause caking of powder products upon storing at elevated temperatures for prolonged periods. In contrast to what its name would suggest, sodium perborate monohydrate contains no water of crystallization. Its molecular structure is [174]:

Figure 78. Bleach performance of sodium perborate vs. temperature [178]
Initial perborate tetrahydrate concentration 1.5 g/L = 150 mg of active oxygen/L

On a per weight basis the monohydrate has a considerably higher content of active oxygen than the tetrahydrate. For this reason, the monohydrate has become the favorite form of perborate in compact detergents.

The use of sodium percarbonate has gained importance in those countries in which boron is either banned or restricted for environmental and regulatory reasons, or negatively discussed. In contrast to sodium perborate, sodium percarbonate is a true peroxohydrate ($Na_2CO_3 \cdot 1.5\ H_2O_2$). In order to achieve a good storage stability for the bleach, coated or stabilized percarbonate must be used.

The salts of peroxomono- and peroxodisulfuric acid and peroxomono- and peroxodiphosphoric acid are not significant as detergent bleaches. This results largely from their insufficient bleaching power in wash liquor, either because they are insufficiently hydrolyzed to hydrogen peroxide in an alkaline medium or because their oxidation potential is too low.

Comparison shows that sodium perborate and sodium percarbonate have the most preferred prerequisites for use as a detergent bleach additive. Oxygen bleaches have been reviewed [174 – 177].

The concentration of bleach-active hydrogen peroxide anion increases with pH value and temperature. Sodium perborate exhibits significantly less bleaching efficiency at temperatures below 60 °C. Even at low temperatures (i.e., where the reaction equilibrium is unfavorable), hydrogen peroxide anions are present in the wash water, but show only modest bleaching power (Fig. 78). The bleaching effect also increases markedly with increasing perborate concentration (Fig. 79) and time.

Figure 79. Bleach performance of sodium perborate vs. concentration (red wine soil) [178]

Many attempts were made in the 1980s to improve the performance of a detergent by using organic peroxy acids, for example, monoperoxyphthalic acid and diperoxydodecanedioic acid (DPDDA) salts, as bleach components:

Monoperoxyphthalic acid monomagnesium salt

Diperoxydodecanedioic acid sodium salt

With these it is possible to obtain significant bleaching at a temperature as low as 30 °C. However, for several reasons (dye damage and cost effectiveness) a technical and commercial breakthrough with these peroxyacids has not been achieved so far.

Hypochlorite is used for bleaching in many global regions where laundry habits, such as cold water washing, cause sodium perborate to be less effective. In an alkaline medium, hypochlorite bleaches are converted to the hypochlorite anion:

$$HOCl + OH^- \rightleftharpoons ClO^- + H_2O$$

Hypochlorite bleach chemistry and applications have been reviewed [179 – 181].

Hypochlorite can be used in either the wash or the rinse cycle at concentrations between ca. 50 and 400 mg/L active chlorine (Fig. 80) and a wash liquor ratio (bath ratio) between 1 : 15 and 1 : 30.

Figure 80. Recommended concentrations of active chlorine as a function of wash temperature [182]
a) Maximum concentration of application; b) Minimum concentration of application
"Active or available chlorine" is calculated as twice the actual weight percent of chlorine in the hypochlorite molecule

Normally, an aqueous solution of sodium hypochlorite (NaOCl) is used as a source of active chlorine. Organic chlorine carriers (e.g., sodium dichloroisocyanurate), which are hydrolyzed to hypochlorite in an alkaline medium, are only common in automatic dishwashing detergents. Figure 81 shows a comparison of the bleaching properties of sodium hypochlorite and sodium perborate as a function of temperature and pH value.

Figure 81. Stain removal comparisons
□ Hypochlorite (200 ppm active chlorine) + 0.15 % detergent; ○ Perborate bleach (28 ppm active oxygen) with protease enzymes + 0.15 % detergent; △ 0.15 % Detergent only[183]

One of the major advantages of powdery sodium perborate over liquid sodium hypochlorite is the fact that whereas the latter must be added separately in either the wash or the rinse cycle, perborate can be incorporated directly into a powder laundry product. This results in a mild color-safe bleach. By contrast, successful addition of chlorine bleach solution, whether in a household or an institutional machine, is heavily dependent on experience of the user and on observing the manufacturer's recommendations. Incorrect dosage of sodium hypochlorite may easily occur, and this may cause significant damage to laundry and colors. A further advantage of sodium perborate is its long shelf life, whereas sodium hypochlorite solutions have limited storage stability, which depends very much on the content of impurities, particularly traces of heavy metal ions. On the other hand, hypochlorite bleaches can be used in both wash and rinse cycles independent of temperature. They provide effective bleaching and disinfection (hygiene) even at very low temperature. However, because of its great reactivity and extraordinarily high oxidation potential, sodium hypochlorite, in contrast to sodium perborate, may cause problems with textile dyes and most fluorescent whitening agents, both of which often show poor stability in the presence of chlorine. Studies of washing and bleaching habits show that peroxide bleach use dominates in Europe, chlorine bleach being used predominantly in Mediterranean countries. Hypochlorite bleach in either the wash or the rinse cycle is still the preferred bleaching agent in a large part of the world (cf. Table 18). The use of peroxide ("oxygen") bleach in laundry products has increased significantly in the USA, Japan, and other regions of the world during the 1980s and 1990s.

3.3.2. Bleach Activators

To achieve satisfactory bleaching with sodium perborate and sodium percarbonate at temperatures $\leq 60\ ^{\circ}C$, so-called bleach activators are commonly utilized. These are mainly acylating agents incorporated in laundry products. When present in a wash liquor of pH value 9–12, these activators preferentially react with hydrogen peroxide (perhydrolysis) to form organic peroxy acids in situ. As a result of their higher oxidation potentials relative to hydrogen peroxide, these intermediates demonstrate effective low-temperature bleaching properties. Due to the low concentration, resulting from the in situ generation, these peroxyacids are much less aggressive to fabric dyes and fluorescent whitening agents than sodium hypochlorite. However, activated peroxy bleach systems may adversely affect the color fastness of fibers treated with some specific dyes upon multiple washing [184]. Among the wide variety of bleach activators investigated [185], only the following compounds have been incorporated on a large scale in laundry products worldwide:

Tetraacetylethylenediamine (TAED) [186].

Sodium *p*-nonanoyloxybenzenesulfonate (NOBS) [193]

The first activator reacts with hydrogen peroxide according to the following scheme to produce peroxyacetic acid:

Table 18. Washing habits in different regions

Washing conditions	United States	Japan	Europe
Washing machine	vertical axis/agitator type	vertical axis/pulsator type	horizontal axis drum type
Heating equipment	no	no	yes
Fabric load, kg	23–5	4–8	2–5
Amount of water, L	medium loads: ca. 50–60 large loads: ca. 65–75	low: 30 high: 65	low: 10–16 high: 20–25
Total water consumption, L (regular cycle)	120	120–150	55–90
Wash liquor ratio	ca. 1 : 25	ca. 1 : 10–1 : 15	ca: 1 : 4–1 : 10
Washing time, min	8–18	5–15	50–60 (90 °C) 20–30 (30 °C)
Washing, rinsing, and spinning time, min	20–35	15–35	100–120 (90 °C) 50–70 (30 °C)
Washing temperature, °C	hot: 55 (130 °F) warm: 30–45 (90–110 °F) cold: 10–25 (50–80 °F)	5–25	90 60 40 30
Water hardness (average), ppm $CaCO_3$	relatively low, 100	very low, 30	relatively high, 250
Detergent dispenser	mostly no	mostly no	yes
Recommended detergent dosage * ,g/L	1.0–1.2	0.5–0.8	4.5–8.0
g/kg laundry	15–30	5–7	15–35
Peroxide bleach	mostly added separately	mostly dosed separately	mostly incorporated in detergent
Chlorine bleach	added separately	dosed separately	predominantly in mediterranean countries

* In the United States and Japan mostly without bleaching components.

TAED

DAED

Under the conditions of the washing process the reaction activates only two acetyl groups. TAED has been used in laundry products in Europe since 1977 and has became state-of-the-art in many laundry detergents and bleaches. TAED has remained the bleach activator of choice in Europe, whereas NOBS has been predominantly used in the Americas and Asia. The broad spectrum of effectiveness of TAED has been reviewed [187 – 190]. Sodium *p*-nonanoyloxybenzenesulfonate (NOBS) reacts with hydrogen peroxide (is perhydrolyzed) to produce peroxynonanoic acid. Aside from their efficiency regarding improvement of low-temperature bleaching, these bleach activators markedly contribute to enhancing the hygiene of laundry due to the biocidal effect of the peracids generated in situ [191, 192]. The effectiveness of the system sodium perborate–TAED on tea stains as a function of concentration and temperature is shown in Figures 82 and 83.

Figure 82. Bleaching effect as a function of bleach concentration [194]

Figure 83. Bleaching effect as a function of temperature [194]

Perborate–TAED bleach systems are not sufficiently effective at cold washing temperatures used in large regions of the world. However, soaking of the laundry in a detergent containing activated perborate prior to washing can greatly enhance the removal of bleachable stains due to the prolonged time of soaking [195]. The problem of graying of white textiles caused by dye transfer during soaking can be reduced by the addition of perborate–TAED to a detergent.

3.3.3. Bleach Catalysts

Numerous attempts have been made to introduce into sodium perborate and/or percarbonate based laundry products small amounts of catalysts that would increase their bleaching performance, especially at low temperature. In most cases, traces of heavy metal ions have been used. While addition of heavy metal ions alone can indeed cause decomposition of sodium perborate, it does not lead to a better bleach. In fact, bleaching action is usually diminished, and serious fiber and color damage may occur. The patent literature describes a number of examples in which the bleaching power of sodium perborate can be increased by heavy metal ion chelates. However, the effectiveness of such systems remains controversial, and catalysts have not been accepted as a part of the washing process. Excellent catalytic bleach enhancement by manganese complexes derived from 1,4,7-trimethyl-1,4,7-triazacyclononane and related ligands has been reported [196]. However, under certain conditions severe dye and fiber damage has been observed in connection with this catalyst system. For this reason detergents using manganese catalysts introduced on the European markets in 1994 were later withdrawn.

Photobleaching with aluminum or zinc phthalocyaninetetrasulfonate represents another form of bleach catalysis. With photobleaching, oxygen from the atmosphere is catalytically activated by the phthalocyanine compound, and the active oxygen generated in turn bleaches oxidizable stains. Suitable conditions for the few detergents that contain photobleaches include — apart from soaking in sunlight — slow drying of the laundry under conditions of high humidity and high light intensity. Therefore, photobleach catalysts are of interest and have been employed in laundry products only in regions with intense solar radiation.

3.3.4. Bleach Stabilizers

Traces of ions such as copper, manganese, and iron catalyze the release of oxygen from bleach systems. This reduces bleach effectiveness and at the same time causes damage to fabrics and dyes. The addition of small amounts of finely divided magnesium silicate largely suppresses this catalysis as a result of absorption of the heavy metal ions. Therefore, magnesium silicate was used in perborate based laundry detergents until the 1980s.

Another possibility for elimination of trace heavy metal ions is the addition of selective complexing agents. Sodium triphosphate has only a modest complexing effect with heavy metal ions and is incapable of causing sufficient bleach stabilization in their presence. By contrast, complexing agents such as sodium hydroxyethanediphosphonate (HEDP) or sodium diethylenetriamine pentakis(methylenephosphonate), as well as other phosphonic acids, exhibit a marked stabilizing effect. The use of these phosphonates is state of the art in many modern laundry products. Amounts of much less than 1 wt % of these strong, selective complexing agents suffice in detergent formulations.

3.4. Further Detergent Ingredients

Surfactants, builders, and bleaches are quantitatively the major components of modern detergents; the auxiliary agents — also called additives — discussed in this section are introduced only in small amounts, each to accomplish its own specific purpose. Today, their absence from detergent formulations is difficult to imagine. They have greatly contributed to making laundry detergents more multifunctional during the last 30 years.

3.4.1. Enzymes

Stubborn proteinaceous stains derived from sources such as milk, cocoa, blood, egg yolk, and grass are resistant to removal from fibers by enzyme-free detergents, particularly when stains have dried-on. So are chocolate and starch-based food stains as well as greasy/fatty stains, particularly in low-temperature washing. Proteolytic, amylolytic, and lipolytic enzymes are usually capable of eliminating such soil without major problems during washing.

Use of enzymes in detergents was first described by Otto Röhm in a 1913 patent application. Enzyme-containing detergents failed to play a major role in the following decades because the only available proteolytic enzyme preparation, a pancreatic extract obtained from slaughtered animals, was too sensitive to the alkaline and oxidative components of detergents. Only in 1959 were Röhm's ideas realized by the use of proteolytic enzymes from fermentation with specific strains of bacteria (*Bacillus subtilis*, later on *Bacillus licheniformis*). These *protease* enzymes were highly resistant to alkali and showed adequate stability at temperatures as high as ca. 65 °C for the time period required by normal washing processes. The first successful detergents on the market containing these proteases were Bio 40 from Gebr. Schnyder in Switzerland in 1959, followed by Biotex produced by Kortman & Schulte in The Netherlands in 1963. Commercial production of detergent enzymes experienced rapid expansion in the years that followed. For example, by 1969 nearly 80 % of the detergents marketed in the Federal Republic of Germany contained proteases as enzyme additives. Industry reduced this proportion to < 50 % as a result of public discussion of certain toxicological concerns. The reservations regarding detergent enzymes have since been addressed and overcome by technical modifications, particularly those involving the delivery form in which enzymes are introduced into detergents: enzymes have been manufactured since 1971 as dust-free granulates, prills, extrudates, or pellets. Today's detergent enzymes are perfectly safe. As a result, nearly all detergents produced in Europe, North America, Japan and many other countries worldwide contain enzymes today. Table 19 provides a brief historical review of the production and application of detergent enzymes.

The effectiveness of proteolytic, amylolytic, and lipolytic detergent enzymes is based on enzymatic hydrolysis of peptide, glucosidic, or ester linkages, respectively. To be well suited for use in detergents, enzymes must exhibit the following properties [197]:

- Activity optimum at alkaline pH
- Efficacy at low wash temperatures of 20–40 °C
- Stability at wash temperatures up to 60 °C
- Stability in the presence of other detergent ingredients, such as surfactants, builders, and activated bleach, both during storage and use
- Low specificity to soils, i.e., a specificity broad enough to enable the degradation of a large variety of proteins, starches, and triglycerides

The activity of enzymes depends on temperature and pH value of the wash bath. Figures 84 and 85 show these respective dependencies of a typical commercially available protease (Savinase) [199].

Figure 84. Activity of Savinase at different temperatures [199]

Table 19. Historical review of the preparation and use of detergent enzymes [197, 198]

Year	Enzyme	Enzyme-containing detergents
1913	Otto Röhm claims the use of tryptic enzymes for detergents	
1931		detergents containing pancreatic enzymes (Burnus, Germany)
1959	Bacterial protease	Bio 49 (Gebr. Schnyder, Switzerland)
1960	Alcalase and Maxatase, microbial proteases made available on a commercial scale by Novo Industri, Bagsvaerd, Denmark and Gist-Brocades, Delft, The Netherlands, respectively	
1963		prewash detergent Biotex (Kortman & Schulte, The Netherlands)
1966		first heavy-duty detergent with microbial proteases
1969		microbial proteases contained in 80 % of all detergents in Germany
1970		severe setback of production of microbial proteases due to public criticism (the "allergy debate")
1972	Additional microbial enzymes made commercially available for use in detergents (amylases)	enzymes in detergents declared to be safe by the German Federal Health Agency
1973	Amylase introduced in Germany	presoak and prewash detergent (Mustang, Henkel, Germany)
1975		market share of enzyme-containing detergents in Germany is 80 %
1975	Liquid proteases for HDL (Maxatase LS, Alcalase L)	
1980s	High-alkaline proteases become available (Savinase, Novo; Maxacal, IBIS; BLAP, Henkel; Purafect, Genencor)	improved efficacy and storage stability for enzymes in heavy-duty detergents
1986	Cellulase (Celluzyme, Novo)	
1987		heavy-duty detergent containing cellulase KAC (Attack, Kao, Japan)
1988	Lipase (Lipolase, Novo)	heavy-duty detergent containing lipase (Hi Top, Lion, Japan)
1988–1989	Bleach-resistant proteases (Maxapem, Gist-Brocades; Durazym, Novo)	
1990s	Enzymes spreading out in detergents worldwide (China, India, South America)	roll-out of multifunctional detergents with more than one enzyme in Europe, Japan, and the USA

Figure 85. Activity of Savinase at different pH values [199]

Ever since detergent-grade enzymes were introduced in the 1960s there has been made considerable progress in terms of

Delivery form
Reduced dust content
Improved alkali resistance
Increased low-temperature activity
Increased activity per unit weight of finished product
Storage stability
Resistance to active oxygen
Effectiveness, functionality
Genetic and enzyme engineering
Decreasing market prices

Enzymes in detergents have therefore meanwhile become state-of-the-art worldwide. Their use spread dramatically in Western Europe, North America, and Japan in the 1970s and 1980s. The 1990s saw also the opening up of the vast detergent markets of China, South America, and India for enzymes [198]. Figure 86 [200] shows the geographical use and value of enzymes in the world. Penetration of enzymes in the U.S. market is 75 %, compared with 95 % for both Europe and Japan. The mainstay of the market have been the protease types.

Only above a certain temperature of the wash bath (mostly 55 °C) does the activity of enzymes decrease, and then very rapidly. Other modes of decomposition present little problems.

For example, intensive research has shown that detergent-grade enzymes currently available are not subject to significant damage during storage or in the wash liquor, provided detergents containing them are properly formulated. Stability problems with respect to anionic surfactants and active oxygen were once the subject of debate, but usually these are readily solved by the proper choice of enzyme type and the appropriate formulation.

Figure 86. Regional detergent enzyme market values (1995, 10^3 $)

Especially in the U.S. and European markets, *amylases* have been added to detergents along with proteases since 1973 to capitalize on the activity of the amylases toward starch-containing soils. Of the different amylases available, only α-amylases are used for detergents. They are able to catalyze the hydrolysis of the amylose and amylopectin fractions of starch, i.e., cleavage of the α-1,4-glycosidic bonds of the starch chain [201]. This eases the removal of starch-based stains by the detergent.

In this context, the *lipases* which, due to their substrate specificity, ease the removal of triglycerides-containing soils are also worth mentioning. The activity of lipases is highly dependent on temperature and concentration. Studies on model greasy soils have shown that removal of solid fats at very low temperatures (e.g., 20 °C) is largely due to the action of added lipases [202]. Lipases produced economically by applying genetic engineering techniques have been commercially available since 1988. The removal of triglyceride-based fatty stains is mostly evident after several washings and drying cycles. At present lipases are contained as further enzymes in premium branded detergents.

Cellulases are capable of degrading the structure of damaged (amorphous) cellulose fibrils, which exist mostly at the surface of cotton fibers after multicycle washing and using. Cotton textiles treated with a cellulase-containing detergent have a smooth surface. For these reasons cellulases are preferably applied in specialty detergents for delicate fabrics or in color heavy-duty detergents for colored textiles. Cellulases also help prevent redeposition of soil on cotton fibers. As such, garments treated with cellulase-containing detergents look new for a longer time, i.e., whites and coloreds do not look dull or dingy after multicycle washing. Today many detergents contain blends of two, three, or even four enzymes [203].

3.4.2. Soil Antiredeposition Agents, Soil Repellent/Soil Release Agents

The principal characteristic expected of a detergent is that it will cause soil to be removed from textile fibers during the washing process. Removed soil is normally finely dispersed, and if a suboptimal detergent formulation is employed, or too little detergent is used, some may return to the fibers. This is termed a wash liquor showing "insufficient soil antiredeposition capability". The problem becomes especially apparent after multicycle washing as a distinct graying of the laundry, which then looks dull and dingy.

Redeposition of displaced soil can be largely prevented by carefully choosing the various detergent components (surfactants and builders), but addition of special antiredeposition agents is also helpful. Such agents act by becoming adsorbed irreversibly, i.e., in a way that prevents their removal by water, on both textile fibers and soil particles. Adherence of the soil to fibers is thereby hindered. This phenomenon is called soil repellent or soil release effect. Classical antiredeposition agents are carboxymethyl cellulose (CMC) derivatives bearing relatively few substituents. Analogous derivatives of carboxymethyl starch (CMS) have played a similar role. These substances are effective only with cellulose-containing fibers such as cotton and blends of cotton and synthetic fibers. With the increasing replacement of these natural fibers by

Figure 87. Influence of specific surfactants on the soil antiredeposition capability of detergents [129]
ΔR indicates the improvement in the soil antiredeposition capability conferred by a given additive
a) Cotton, 95 °C; b) Permanent-press cotton, 95 °C; c) Polyester, 60 °C; d) Polyester/cotton, 60 °C
5 g/L Detergent; 0.2 g/L surfactant; number of wash cycles: 3; time: 30 min

synthetics, on which CMC has virtually no effect, the need arose to develop other effective antiredeposition agents and soil repellents. Some surfactants have been found to be well-suited to the purpose (Fig. 87), as are such nonionic cellulose ethers [204, 205] as the following:

R: CH_3, CH_2CH_3, CH_2CH_2OH, $-CH_2CHOHCH_3$, $-CH_2CH_2CHOHCH_3$

Also anionic derivatives of polymers from terephthalic acid and polyethylene glycol have proved to be very effective soil repellents, particularly on polyester fibers and polyester–cotton blends. They impart hydrophilic properties to these fibers and thus strongly repel oily/greasy soil [206 – 208].

Because of the multitude of fabrics currently on the market, manufacturers supplement most modern detergents with mixtures of anionic and nonionic polymers (e.g., carboxymethyl cellulose–methyl cellulose) and polymers from polyethylene glycol and terephthalic acid and their anionically modified derivatives.

Polymer cobuilders, such as sodium polycarboxylates, and cellulose enzymes have also proved to exert a very good soil antiredeposition effect with cotton fibers.

3.4.3. Foam Regulators

For soap detergents, which are very popular in regions with low per capita income worldwide, foam is understood as an important measure for washing performance. With detergents based on synthetic surfactants, however, soap has lost virtually all of its former significance in the industrialized countries. Nonetheless, most consumers — apart from those using horizontal

axis drum-type washing machines — still expect their detergent to produce voluminous and dense foam. The reason for this seems to be largely psychological (i.e., foam provides evidence of detergent activity and it hides the soil). Consequently, detergents designed for use in vertical-axis washing machines (i.e., products mainly for the non-European market) are quite frequently given the desired foam characteristics by incorporating small amounts of foam boosters. Compound types suited to the purpose include

Fatty acid amides
Fatty acid alkanolamides
Betaines
Sulfobetaines
Amine oxides

In Europe, horizontal axis drum-type washing machines are very common; with such machines, only weakly or moderately foaming detergents are permissible. Thus, foam boosters have lost their former significance in the European market, with the exception of the role they retain in certain specialty detergents (e.g., detergents for hand washables). Especially at high temperature, heavy foaming may cause overfoaming in drum-type machines, often accompanied by considerable loss of active ingredients. Furthermore, large amounts of foam reduce the mechanical action to which laundry is subjected in horizontal axis machines and hence the washing performance. Moreover, excessive foam may result in poor rinsing, spinning, and draining of the washing machine. On the other hand, too little foam must be avoided because consumers have the perception that low foam levels are a sign of poor cleaning performance. A certain level of foam can be beneficial for delicate fabrics to reduce fabric damage. For these reasons, foam regulators — often somewhat incorrectly described as "foam inhibitors" — are commonly added to minimize detergent foaming tendencies.

Ensuring effective foam regulation requires that the regulating system be precisely matched to the other detergent components present. The most difficult cases are surfactants with exceptionally high foam stability, such as alcohol sulfates, alcohol ether sulfates, alkylpolyglycosides, and alkylglucamides. By contrast, an unstable foam, even if present in large amounts, like that produced by LAS or SAS, seldom causes a problem. The principal requirements for a substance to show foam regulating capability are extremely low water solubility and high surface spreading pressure. Typically, an antifoam is a dispersion of hydrophobic solid particles in a hydrophobic liquid (→ Foams and Foam Control). Foam regulators show a wide range of physicochemical properties, but their mechanism of action can usually be explained by assuming that they either force surfactant molecules away from interfaces or they penetrate interfaces that are already occupied by surfactants, thereby creating defects. These defects weaken the mechanical strength of the foam lamellae and cause their rupture.

A great many foam regulators are described in the patent literature, but relatively few have had any real impact. The detergents on the market that are based on LAS/alcohol ethoxylates can be effectively controlled by soaps with a broad chain length spectrum (C_{12-22}). Such soaps have limitations, however, for the following reasons:

1) The foam-depressing activity of soaps is largely due to calcium salts that form during the washing process, with the calcium originating either from hard water or from calcium-containing soil. In other words, satisfactory foam regulation occurs only when a sufficiently high calcium ion content is assured. It is absent when exceptionally soft water is used and when the laundry is only lightly soiled, and foaming problems may result.
2) The foam regulating power of soap is substantially lower with detergents based on anionic surfactants other than alkylbenzenesulfonates (e.g., α-olefinsulfonates, alcohol sulfates, α-sulfo fatty acid esters).
3) When soap is used as a foam regulator, the only complexing agents that can be added as builders are those with limited stability constants; i.e., even in the presence of builders, the calcium ion concentration must remain high enough to permit formation of sufficient lime soap able to act as a foam regulator. An advantage of sodium triphosphate, widely used as a complexing agent in detergents, is that stability constant values for calcium triphosphate complexes are quite low. Other complexing agents (e.g., nitrilo-

triacetic acid, NTA), that have higher stability constants, prevent the formation of foam-regulating lime soaps (Fig. 88).

Figure 88. Foaming behavior in a drum-type washing machine [46]

Foam grading: 0, no foam; 4, foam at the upper edge of the front door; 5, foam in the dispenser; 6, foam overflow

Intensive investigations have shown that specific silica–silicone mixtures or paraffin oil systems are considerably more universal in their applicability and that their effectiveness is independent of both water hardness and the nature of the surfactant–builder system employed [209 – 212]. Therefore, most heavy-duty detergents in Europe have silicone oil and/or paraffins as foam depressors. Soap has almost lost its importance as foam regulator. Silica–silicone systems, frequently called silicone antifoams, are usually commercially available as concentrated powders. They are robust and effective over a wide range of washing conditions for a wide range of laundry products at quite low levels in the formulation (typically 0.1–0.4 %). The key silicone oils used for antifoams are dimethylpolysiloxanes [213]. Silicone antifoam powders are easily processed as postaddition components for detergent manufacturing. It is not recommended to process them in the detergent slurry during production, because the antifoam performance is largely destroyed during spray drying.

3.4.4. Corrosion Inhibitors

Washing machines currently on the market are constructed almost exclusively with drums and laundry tubs of corrosion-resistant stainless steel or with an enameled finish that is inert to alkaline wash liquors or plastic. Nevertheless, various machine components are made of less detergent resistant metals or alloys. To prevent corrosion of these parts, modern detergents contain corrosion inhibitors in the form of sodium silicate. The colloidal silicate that is present deposits as a thin, inert layer on metallic surfaces, thereby protecting them from attack by alkali.

3.4.5. Fluorescent Whitening Agents (see also → Optical Brighteners)

Properly washed and bleached white laundry, even when clean, actually has a slight yellowish tinge. For this reason, as early as the middle of the 19th century, people began treating laundry with a trace of blue dye (blueing agents, e.g., ultramarine blue) so that the color was modified slightly and a more intense visual sensation of improved whiteness was produced. Blueing agents are still popular in some regions of the world. Modern detergents contain fluorescent whitening agents (FWA), also known as *optical brighteners* (→ Optical Brighteners), to accomplish the same purpose. Fluorescent whitening agents are organic compounds that convert a portion of the invisible ultraviolet light into longer wavelength visible blue light. It is well known that the yellowish cast of freshly washed and bleached laundry is a result of partial absorption of the blue radiation reaching it, resulting in reflected light that is partially deficient in the blue region of its spectrum. The radiation emitted by optical brighteners makes up for this deficiency, so that the laundry becomes both brighter and whiter (Fig. 89).

This process of compensating for differences in yellow and blue radiation is fundamentally different from treatment with a blueing agent (washing blue). The latter entails subtractive absorption of yellow light, which results in an overall reduction in brightness (Fig. 90).

Figure 89. Remission–emission curve of a bleached fabric after application of a fluorescent whitening agent [125]
a) Bleached fabric; b) Fabric treated with small amounts of whitener; c) Fabric treated with large amounts of whitener

Figure 90. Remission curve of a bleached fabric after application of ultramarine blue [125]
a) Bleached fabric; b) Weakly blued fabric; c) Intensely blued fabric

Limits exist for the extent of whitening that can be achieved by fluorescent whitening agents. This is due in part to the fact that these agents are themselves dyes that exhibit a certain extent of reflectance in the visible region in addition to their emission. Thus, any agglomeration or buildup of fluorescent whitening agent on the fibers eventually becomes apparent. Furthermore, the absorption edge gradually shifts into the visible region of the spectrum, leading to emission at higher wavelengths. These factors can work in combination with the innate color of the fabric, however, and eventually result in a visible shift of the hue (discoloration).

The major commercially available optical brighteners for laundry products are based on four basic structural frameworks: distyrylbiphenyl, stilbene, coumarin, and bis(benzoxazole). Table 20 provides an overview of the most important optical brighteners. Those mentioned here are estimated to cover more than 95 % of optical brighteners for laundry products on the market.

The application of FWA in the wash liquor is essentially a dyeing process (FWA are actually dyes). In the case of cotton and chlorine-resistant FWA, binding occurs through the formation of hydrogen bonds to the fibers. Permanent-press easy-care cotton is generally less susceptible to the effects of FWA. Whitening effects achieved with polyamide whiteners, and particularly polyester whiteners (which tend to be less adsorbed), are due largely to the diffusing power of whitening agent molecules present at the fiber surfaces.

Fluorescent whitening agents are evaluated not only on the basis of their affinity for the relevant fibers, but also on their stability and fastness. "Stability" means their resistance to chemical change during the washing process prior to their adsorption on fibers. "Fastness" refers to their chemical resistance after adsorption. Of primary concern is fastness against light and oxygen, as well as good oxygen stability and, in countries where chlorine bleach is used, fastness and stability to hypochlorite bleaches.

Most detergents currently on the market contain fluorescent whitening agents. A concern to detergent formulators is the difficulty to define optimal FWA type(s) and concentration in laundry detergents for sufficient whiteness maintenance because of the wide variety of washing habits and fiber types used for white textiles [215]. The use of FWA-containing detergents on certain pastel fabrics can cause unwanted color shifts; for this reason special FWA-free detergents are very popular [e.g., color detergents (see Section 4.1.5) and detergents for woolens)].

3.4.6. Dye Transfer Inhibitors

Frequently used dye transfer inhibitors are poly(*N*-vinylpyrrolidone) and poly(vinylpyridine *N*-oxide). These inhibitors form stable complexes with dye molecules that detach from colored textiles and diffuse into the wash bath. As such, the dye transfer inhibitors impede the re-adsorption or redeposition of the dyestuff on other textiles. The result is that white and colored garments look new longer after multicycle

Table 20. Summary of key fluorescent whitening agents for laundry products [214]

Structure	Chemical Name
	4,4′-di(2-sulfostyryl)biphenyl disodium salt
	4,4′-Bis[[6-anilino-4-(methylamino)-1,3,5-triazin-2-yl]amino]stilbene-2,2′-disulphonic acid, disodium salt
	4,4′-bis[[6-anilino-4-[(2-hydroxyethyl)methylamino]-1,3,5-triazin-2-yl]amino]stilbene-2,2′-disulphonic acid, disodium salt
	4,4′-Bis[[2-anilino-4-[bis(2-hydroxyethyl)amino]-1,3,5-triazin-6-yl]amino]stilbene-2,2′-disulfonic acid, disodium salt
	4,4′-Bis[(2-anilino-4-morpholino-1,3,5-triazin-6-yl)amino]-2,2′-stilbenedisulfonic acid, disodium salt
	4,4′-bis[(4,6-dianilino-1,3,5-triazin-2-yl)amino]stilbene-2,2′-disulphonic acid, disodium salt
	2,5-bis(benzoxazol-2-yl)thiophene
	7-diethylamino-4-methylcoumarin

washing. A dull and dingy look of the textiles is avoided.

3.4.7. Fragrances

Fragrances were first added to detergents in the 1950s. Their presence is more than simply a fad or a matter of fashion. Thus, apart from their role in providing detergents with a pleasant odor, an important function of fragrances is to mask certain odors arising from the wash liquor during washing. This is particularly important because most washing machines are installed in the living areas of homes. Fragrances are also intended to confer a fresh, pleasant odor on the laundry itself. For this, long-lasting fragrances on dry laundry, resulting either from detergents or from fabric softeners have become a more and more important factor in the 1990s.

Detergent fragrances are generally present only in very low concentrations, usually $< 1\,\%$ in powder products. They are all complex mixtures of many individual ingredients (Table 21).

Table 21. Hypothetical formulation of a fragrance blend for detergent use

Ingredient	Quantity, g
Cyclohexyl salicylate	200.0
Iso E Super	100.0

Anisaldehyde	5.0
Cyclovertal	3.0
Styrolyl acetate	5.0
Isobornyl acetate	15.0
Ambroxan	2.0
Herbavert	15.0

Several factors are involved in establishing the composition of a fragrance mixture apart from odor and the cost of the often expensive individual components. In particular, the detergent formulation must be taken into careful account, as must the properties of the fabrics to be washed. Chemical stability relative to other detergent ingredients is especially important, as is the limited volatility of the individual fragrances. Temperatures to which the detergent will be exposed during storage must also be considered.

The fragrance industry has at its disposal for the preparation of detergent fragrance oils not only a large selection of synthetic compounds, but also a wide range of natural fragrances. The overall selection is, nevertheless, restricted considerably due to the instability of many fragrances and the fact that some have a tendency to discolor detergents to which they are added. There are also restrictions for toxicological and ecological reasons (cf. Chaps. 10 and 11).

3.4.8. Dyes

Until the 1950s, powder detergents were more or less white, consistent with the color of their components. Thereafter, products were commonly encountered in which colored granules were present along with the basically white powder: certain components had been deliberately dyed to make the finished detergent more distinctive, featuring speckles. Uniformly colored detergents have also appeared on the market, and the idea of introducing coloring agents has become quite common. The preferred colors for both powders and liquids are blue, green, and pink.

There are two important criteria for selecting a coloring agent:

1) Good storage stability with respect to other detergent components and to light and temperature
2) No significant tendency to adversely affect textile fibers through adsorption after multiple washing

3.4.9. Fillers and Formulation Aids

The usual *fillers* for powder detergents are inorganic salts, especially sodium sulfate. Their purpose is to confer the following properties on a detergent:

Figure 91. Per capita consumption of detergents in 1996 (kg/a)

Flowability
Good flushing properties
High solubility
No caking of the powder even under highly humid conditions
No dusting

Compact detergents usually contain no fillers.

Formulation aids are materials required in the manufacturing of liquid detergents. The most important of these have the assignment of ensuring through their own hydrotropic characteristics that the other detergent components can be combined in a stable way in an aqueous environment. Above all, these ingredients must prevent phase separation occurring with time, and precipitation occurring as a result of shifts in temperature. Commonly used materials include short-chain alkylbenzenesulfonates (e.g., toluenesulfonate and cumenesulfonate) and, less frequently, urea, as well as low-molecular mass alcohols (ethanol, 2-propanol, glycerol) and polyglycol ethers [poly(ethylene glycols)]. These alcohols are frequently called solubilizers.

4. Laundry Products

Laundry products currently on the market in various parts of the world can be classified into the following groups from a product standpoint:

Figure 92. World production of individual heavy-duty detergents (in 10^3 t)
(source: Ciba Speciality Chemicals Ltd., Switzerland)

Figure 93. Detergent production, world total (10^3 t)
(source: Ciba Speciality Chemicals Ltd., Switzerland)

Heavy-duty detergents
Specialty detergents
Laundry aids

Quite large differences exist in the per capita consumption of detergents in various countries of the world. As depicted in Figure 91, it amounted to 2–3 kg/a in countries such as Brazil, China, and Russia and to more than 10 kg/a in Mexico and some European countries in 1997 [216, 217].

4.1. Heavy-Duty Detergents

The category of heavy-duty detergents includes those detergent products suited to all types of laundry and to all wash temperatures. They are offered in the delivery forms of conventional powders, extrudates, tablets, bars, and liquids and pastes. Figure 92 indicates that worldwide powders have been the dominant delivery form of detergents over the years. They account for ca. 65 % of the world production of detergents. Compact powders worldwide accounted for 24 % of total detergent powder production in 1998. Depending on quality, product concept, manufacturing process, local standards, local regulations, and voluntary agreements, great differences are found from one formulation to another. For example, detergent manufacturers market laundry detergents with and without phosphate in various regions and countries for ecological and regulatory reasons. Figure 93 provides an overview of global production shares of individual heavy-duty detergent types in 1994 and 1998.

The world production of laundry detergents amounted to 21.5×10^6 t in 1998. Table 22 shows the proportions of the tonnages of individual delivery forms of detergents in 1994 and 1998. As can be seen, the total produced volume remained nearly constant in the 1990s worldwide.

4.1.1. Conventional Powder Heavy-Duty Detergents

Significant differences in composition exist among powder heavy-duty detergents around

the world. An approximate breakdown of detergent formulations for various global regions is provided in Table 23.

Figure 94. Percentage of wash loads versus washing temperature in Germany (source: Leading German Market Research Institute)

Recommended detergent dosages in Europe generally lie between 3 and 8 g detergent per liter of wash water, whereas values of 0.5–1.5 g/L are usual in the Americas and Eastern and Southern Asia. There are a number of reasons for the latter being so much lower; for example, differences in washing habits (different washing machines, handwashing), softer water, higher bath ratios, separate addition of bleach, e.g., hypochlorite solution or sodium perborate, and different detergent formulations. Detergents in North America, Japan, and Brazil are designed for agitator and impeller type washing machines (cf. Chap. 13). These detergents lack foam suppressors. They sometimes even contain foam boosters instead.

The rise in popularity of ever more colored and easy-care fabrics in the last 30 years, along with the trend toward energy conservation, has resulted in a large decline in the once common European practice of washing at 95 °C, while the 30–60 °C wash temperatures have significantly gained favor. The change is illustrated in Figure 94 for the time period 1972 to 1995 in Germany. A similar trend from hot ($\geq$ 50 °C) to warm (27–43 °C) and cold washing is apparent in the USA (Fig. 95). Detergent manufacturers have responded to these changes by increasing

the content of surfactants that are effective in low-temperature washing, as well as by adding various enzymes, bleach activators, soil repellents, and phosphonates. Detergents have become more and more multifunctional over the last decades, particularly those for use at low washing temperatures.

Figure 95. Home laundry washing temperature trends in the USA

4.1.2. Compact and Supercompact Heavy-Duty Detergents

Apart from a few minor and temporary attempts in Japan, Germany, and the USA in the 1970s and early 1980s [145], this heavy-duty detergent category was introduced on a large scale for the first time in Japan in 1987. Within a couple of years it almost completely replaced the conventional powders. The wave of compact detergents reached Europe in 1989. North America followed shortly afterwards [220]. The global introduction of compact and supercompact powder detergents in the late 1980s and early 1990s has had a major impact on detergent categories of large markets such as Japan, Europe, and the USA, as well as on composition and manufacturing processes of heavy-duty detergents [220]. Production processes of concentrated detergents are described in Chapter 6. A comparison of the composition of conventional versus compact heavy-duty detergents in Europe is depicted in Table 24 [216, 217]. For reasons of significantly reduced recommended dosage along with increased detergency performance compact detergents have markedly higher contents of surfactants, active oxygen for bleach, bleach activators, and enzymes than conventional detergents. On the other hand, the total level of alkaline builders has been reduced and the conventional filler/processing aid sodium sulfate has been omitted to a large extent (Fig. 96 [216, 217]). The apparent density of most compact detergents is above 0.75 kg/L. Most of the first-generation compact detergents were produced by the method of downstream compaction of tower powder.

Table 24. Composition of conventional versus compact heavy-duty detergents in Europe, % [216]

Ingredients	Conventional	Compact
Anionic and nonionic surfactants	10–15	10–25
Builders	25–50	25–40
Cobuilders	3–5	3–8

Bulk density, g/L	500–650	600–900

Figure 96. Formulations of heavy-duty detergents [216]

Heavy-duty detergents featuring bulk densities of from 0.8 to 1.0 kg/L are called supercompact detergents or second-generation compact detergents. The prevailing manufacturing methods used are wet granulation/compounding

Figure 97. Consumer-relevant characteristics of heavy-duty detergents

Figure 98. Individual heavy-duty detergents in Europe, market shares (value) 2000 in % [218]

and extrusion. Supercompact detergents have made their way worldwide since 1992 and are meanwhile state of the art in many countries. Consumer relevant properties of (super)compact vs. conventional detergents are depicted in Figure 97 [216, 218]. Market shares of compact/supercompact powder heavy-duty detergents in Europe as compared with conventional powders and liquid detergents are indicated in Figure 98 [218] for 2000. The market shares significantly vary from country to country and from region to region. In the USA compact powders accounted for 80 % of total detergent powders, whereas their share in Japan was even 92 % in the total powder category in 1998.

Sodium triphosphate has been increasingly losing its importance as a key ingredient in detergents in Europe, the USA, and some East-Asian countries since the mid-1980s. 1998 market shares of nonphosphate powder detergents in most European countries are shown in Figure 99 [220]. Triphosphate has been replaced mainly by zeolite A, special silicates, sodium carbonate, specific polycarboxylates, and citrate (see Section 3.2). A key driving force for the increasing market shares of nonphosphate powder heavy-duty detergents has been the proliferation of supercompact detergents [216, 217]. Generally, the use of (super)compact detergents has contributed to decreasing their influx into wastewaters, much to the benefit of the environment [226].

Figure 99. Market shares of nonphosphate HDD powders in Europe in 1998 [220]

4.1.3. Extruded Heavy Duty Detergents [225]

Extruded detergents have been an innovative and unconventional delivery form of second-generation compact detergents. The large-scale extrusion process for detergents was applied for the first time in 1992 and is described in Chapter 6 [227 – 230]. Extruded detergents have since then been marketed under the registered trademark of "Megaperls" by Henkel throughout Europe.

Extruded detergents feature spherical particles of uniform particle size (for example 1.4 mm) whereas conventional spray-dried detergent powders and granulated supercompact detergents are characterized by a broad particle size distribution. The density of an extruded particle is approximately 1.4 kg/L. Extruded detergents have one of the highest densities achieved in detergent manufacturing.

Apart from being an extraordinary basis for manufacturing supercompact products, extruded detergents feature additional advantages such as complete absence of dust particles, very high homogeneity, no segregation of particles, and excellent free-flowing characteristics. Extruded detergents allow anionic surfactant contents of more than 20 % along with very high densities.

4.1.4. Heavy-Duty Detergent Tablets [231 – 234]

Busier consumer lifestyles have increased demand for laundry products that emphasize convenience and ease of use, as exemplified by detergent tablets. Apart from very few regional distributions in the past, detergent tablets were first introduced on a large scale in Europe in late 1997. Ever since they have spread out on the European market and held a share of 10 % in the heavy-duty detergent category by mid-2000. The Japanese, Canadian, and U.S. markets saw their introduction during the year 2000. In the wide field of laundry products, tablets meanwhile also cover the categories of bleach boosters and water softeners in Europe.

Consumer-relevant characteristics of tablets are ease of dispensing and convenience in handling, i.e., no dosing and dispensing aids are needed. Other advantages include precise dosing, smaller packages as compared with powder products due to the highly concentrated form, extra portability, and more accurate sense of how many washes remain in the detergent box.

Tablets are the most compact delivery form of nonliquid detergents. They have densities of 1 to 1.3 kg/L. This results in benefits in terms of lower packaging volume, ease of transportation and storage, and reduced shelf space. Detergent

tablets therefore belong to the supercompact detergent category (see Section 4.1.2).

One of the key requirements of laundry detergent tablets is fast disintegration. Upon their first contact with water, be it in the washing machine dispenser of a European drum-type washer or in the basket of top-loading agitator (North America) or pulsator machines (East Asia), tablets must disintegrate within seconds or at least within a minute or so. This is a necessary prerequisite for the next step of dissolving, particularly with regard to the short washing times used in Japan, the USA and, recently, Europe. Special precautions must therefore be taken to avoid intermediate formation of viscous liquid-crystalline phases (gelling effect) of the surfactants in the tablet detergent during contact with water. To enable fast disintegration laundry detergent tablets generally contain special disintegrants. These can be classified into four groups:

1) Effervescents such as carbonate/hydrogencarbonate/citric acid
2) Swelling agents like cellulose, carboxymethyl cellulose, and cross-linked poly(*N*-vinylpyrrolidone)
3) Quickly dissolving materials such as Na (K) acetate or Na (K) citrate
4) Rapidly dissolving water-soluble rigid coating such as dicarboxylic acids

or combinations therof.

Another specific demand made on heavy-duty detergent tablets is sufficient hardness to enable handling during packaging, transportation, and in-home use. The conflicting desired properties of sufficient hardness and fast disintegration have to be well balanced. Usually, laundry detergent tablets have weights of ca. 35 to 45 g and diameters in the range of 40 to 45 mm. The most common recommended dosage in Europe is two tablets per wash cycle. One- and two-phase (colored) tablets are available on the market. Two-phase tablets allow separation of certain detergent ingredients that otherwise might adversely affect each other during storage, for example, enzymes and activated bleach.

In terms of their composition, heavy-duty detergent tablets differ from other supercompact detergents mostly with regard to the disintegrants. Table 25 lists the composition of European detergent tablets. All compact heavy-duty detergents in Europe have been nonphosphate zeolite-based thus far [216]. The reappearance of phosphate in the detergent tablet category in Europe (see Table 25) may therefore be considered a remarkable development [231].

Table 25. Composition of heavy-duty detergent tablets on the European market [231]

Ingredients	Zeolite-based, %	Phosphate-based, %
Surfactants	13–18	15–18
Bleaching agents	13–15	12–16

Sodium polycarboxylate	2–3	2
Disintegrants	5–17	0–12
Enzymes	2–4	2–3

Figure 100. Market Shares (value) of Color Heavy-Duty Detergents in the Total HDD Category (source: Leading International Market Research Institute)

4.1.5. Color Heavy-Duty Detergents

In 1991, a new category of heavy-duty detergents appeared on the West European market, for which the name color detergents was coined. So far, this type of compact detergent has mainly spread out on the market in Western Europe. 1999 market shares of color detergents in some countries on the European continent are shown in Figure 100. Color detergents differ from conventional European heavy-duty detergents in that they contain neither bleach nor optical brighteners and in that they feature specific dye transfer inhibitors such as poly(*N*-vinylpyrrolidone) or poly(vinylpyridine *N*-oxide).

Color detergents are recommended and used for washing colored laundry, for which improved color care is claimed.

4.1.6. Liquid Heavy-Duty Detergents

Liquid detergents have been common in the USA since the 1970s for a variety of reasons. Today, the USA is the largest single market of liquid heavy-duty detergents (HDL) in the world. The market share of HDL in the USA was some 50 % in 1999. Until 1987, such products were insignificant in Europe, although liquid heavy-duty detergents had been available on the European market since 1981. In 1998, liquid heavy-duty detergents represented 12 % of the market in Europe, and their worldwide share was 14 % of total detergent production.

Liquid heavy-duty detergents are distinctive because of their usually high surfactant content (up to ca. 50 %). They rarely contain builders such as zeolite or triphosphate and are generally devoid of bleaching agents, the latter for reasons of loss of active oxygen and incompatibility with enzymes during storage. They are most effective in removing greasy and oily soil, especially at wash temperatures below 60 °C. A comparison of the detergency characteristics of European liquid and powder heavy-duty detergents is depicted in Table 26 [119]. From the characteristics of the two types of detergent it is obvious that both products have different but distinct fields of optimal performance. Depending on washing habits, HDL are alternatives to powders especially for washing in the lower temperature range [235].

HDL are marketed both with and without added builders. Formulations for liquid heavy-duty detergents with (structured) and without builders (unstructured) in Europe are given in Table 27 [216]. Liquid detergents with builders typically contain 15–30 % surfactants; the total amount of surfactants in products without builders can be as high as 50 %. The unstructured liquid detergents have continued to dominate the market. Besides having a high content of synthetic surfactants, they include a large proportion of soap with a defined carbon chain length as a water-softening component, as well as ingredients needed as formulation aids. The total content of washing active components can be as high as 60 %. The liquid products still contain water and are free of bleaching agents. Although many patents have been filed for liquid detergents that contain bleaching agents, none have yet been marketed successfully. In common with the increasing multifunctionality of powders, liquid heavy-duty detergents show a steady trend towards a higher enzyme content and incorporation of more types of enzymes.

Table 26. Performance of powder versus liquid heavy-duty detergents

Product characteristics	Powder 60–90 °C	Liquid 30–60 °C

Stabilizers	+/–	+/–
Fragrance	+	+
Minors, water	30–50	30–50

Increasing concentrations of total active ingedients have been introduced in liquid detergents in the first half of the 1990s, although the degree of compaction has not been as drastic as with powdered products. Conventional liquid heavy-

duty detergents still dominate the market in some European countries.

The physical appearance of liquid laundry detergents remained unchanged for a long time. They were marketed as low-viscosity (250–300 mPa · s) products with a Newtonian flow behavior. This changed with the launch of detergent gels in Europe. Gel-like pourable heavy-duty detergent concentrates that feature a specific rheological behavior represent a new delivery form in the liquid segment in Europe [236]. These gel detergents have much higher viscosities than conventional HDL (ca. 1500–3000 mPa · s). Gels were introduced in almost all European markets in 1997. Because of their high viscosity and rheological properties gels show improved detergency performance in pretreating stains as compared with conventional HDL [236]. Due to the continuous increase in the use of liquid concentrates and the reduction of the recommended dosage, it has been possible to reduce package sizes without decreasing the number of wash loads per package. This has resulted in large savings on packaging material and transportation costs.

4.2. Specialty Detergents

Specialty detergents play a relatively minor role outside Europe, but they are quite important in Europe.

Specialty detergents are products developed for washing specific types of laundry. Such detergents are generally used in washing machines but also for hand washing. They usually require the use of special washing programs (e.g., a wool cycle to prevent felting or a gentle cycle to prevent wrinkling). They can be characterized by the fact that fabric care ranks high and is a more important feature than with heavy-duty detergent for which soil and stain removal is the key characteristic.

4.2.1. Powder Specialty Detergents

Distinction is made among products of the following types:

Detergents for delicate and colored laundry
Detergents for woolens
Detergents for curtains
Detergents for washing by hand

Many of these products are appropriate for either machine or handwashing. Most of them are marketed with an average bulk density of 0.4–0.5 kg/L.

Detergents specially designed for *delicate and colored laundry* contain neither bleach nor fluorescent whitening agent which may adversely affect sensitive dyes used with some of these fabrics. These detergents are particularly useful for laundry colored with dyes sensitive to oxidation or for pastel fabrics that otherwise might experience color shifts if treated with fluorescent whitening agents. Most products today contain cellulases, which help fabrics look new longer and keep colors bright. Dye transfer inhibitors are added to some specialty detergents.

Detergents for *wool* are primarily intended for use in washing machines. Particular care must be exercised to prevent damage to the sensitive fibers that constitute natural wool, including applying low-temperature washing, short washing times, high bath ratios, and avoiding vigorous mechanical action.

High-foaming detergents for *washing by hand* are intended for washing small amounts of laundry in the sink or in a bowl. Due to the increased number of household washing machines, the use of specialty handwashing detergents has been gradually declining in Europe through the last decades. Their share was ca. 3 % in the entire detergent category in 1999.

Table 28 provides the compositions of various types of specialty detergents.

4.2.2. Liquid Specialty Detergents

Liquid specialty detergents have been on the market in Europe for a long time. Some liquid specialty detergents are intended for handwashing. However, most specialty liquid products are intended for washing machine application, e.g., detergents for woolens. The latter may be free of anionic surfactants, in which case they usually contain mixtures of cationic and nonionic surface active agents. The cationic agents act as fabric softeners to help keep wool soft and fluffy. Table 29 describes typical formulations for liquid specialty detergents.

Table 28. General formulations of West European powder specialty detergents

Ingredients	Composition, %			
	Detergents for delicate textiles	Detergents for woolens	Detergents for curtains	Handwashing detergents
Anionic surfactants (alkylbenzenesulfonates, fatty alcohol ether sulfates)	5–20	10–20	10–16	12–25

Fragrances, dyes	+	+
Water	60–70	60–80

4.3. Laundry Aids

Laundry aids are products developed to meet the varying needs of often widely divergent washing habits and practices in different parts of the world. For example, most powdered heavy-duty detergents in Europe contain oxygen bleach. Most in the Americas, Africa, and Asia do not, and hence separate addition of bleach may be required. Depending on their use, laundry aids can be divided into the following categories:

Pretreatment aids (prespotters, water softeners)
Bleaches
Detergent boosters
Fabric softeners
Stiffeners
Laundry dryer aids
Refreshing products for dryer application
Odor removers

The global laundry aids market was worth \$ 38.7×10^9 in 1998. Western Europe accounted for 30.4 %, while the USA ranked second with 20.8 % of global sales [237].

4.3.1. Pretreatment Aids

The most important pretreatment aids are soil and stain removers and water softeners. Special presoaking agents that were frequently applied in the past have gradually lost their market importance in the industrialized countries.

Table 30. Frame formulations of soil and stain removers in Europe and the USA

Components	Composition, %				
	Europe		USA		
	Pastes	Sprays	Liquid/sprays	Sticks	Gels
Anionic surfactants (alkylbenzenesulfonates, alcohol sulfates, soaps)	15–30		0–3	10–15	0–0.5
Nonionic surfactants (nonylphenol ethoxylates, alcohol ethoxylates, amine oxides)	3–10	15–40	1–15	25–35	8–45

Enzymes			0.2–1	2–3	0–2
Dyes, fragrance, stabilizers, water	balance	balance	balance	balance	balance

Soil and stain removers , also called prespotters or pretreatment aids, are frequently products with high surfactant contents. Their direct application helps removing greasy and/or bleachable stains (Table 30). Such products are applied to soiled areas prior to washing. They are supplied as pastes, sticks, or aerosols or in trigger spray bottles. The major targets of such products are fabrics that require low-temperature washing. The regular use of soil and stain removers can also help prevent the buildup of soil on problem areas such as shirt collars and cuffs after multicycle wear/washing.

Spray stain removers mainly consist of mixtures of solvents and surfactants. Solvents similar to those employed in dry cleaning loosen grease so that it can subsequently be emulsified by appropriate surfactant blends. Sprays generally work more rapidly than paste products. Proper application of such products prevents formation of undesirable rings around stains, a consequence that is nearly unavoidable when stains are subjected to local treatment with pure solvents instead.

Water softeners are used both in the USA and in Europe. European manufacturers recommend that these softeners be used in combination with detergents for applications involving water of medium to high hardness. However, the great majority of heavy-duty laundry detergents contain sufficient builders and cobuilders to prevent build-up of lime deposits upon multicycle washing even in hard water. European water softeners generally contain ion exchangers, usually zeolite A and polymeric carboxylic acids (Table 31).

Table 31. Frame formulation of water softeners in Europe

Ingredients	Composition, %
Zeolite A	45–60
Sodium polycarboxylate	10–15
Sodium silicate	10–15
Sodium sulfate, minors, water	balance

4.3.2. Boosters

Boosters are products that can be added separately to detergents to exert specific influences on the washing process and thereby improve its effectiveness. The principal types of boosters offered on the market are bleaching agents and laundry boosters.

Bleaching agents are found worldwide on the market. They have been common in the Americas and Asia for a long time, where they are available in both powder and liquid

form. Powder bleaching agents generally contain sodium perborate or sodium percarbonate (Table 32), whereas most liquid bleaching agents are dilute solutions of sodium hypochlorite or hydrogen peroxide. Bleaches are usually applied optionally when needed along with detergent. Sodium hypochlorite is to be used for whites only, whereas hydrogen peroxide solutions and powder and tablet peroxygen bleaches (perborate/percarbonate) are considered color-safe products.

Table 32. Frame formulations of all-fabric bleaches in the USA

Ingredients	Composition, %	
	Powders	Liquids
Builders (sodium carbonate, zeolite, sodium citrate, sodium silicate)	60–75	–
Anionic surfactants (alkylbenzenesulfonates, alcohol sulfates, alcohol ether sulfates)	5–15	2–10
Nonionic surfactants (alcohol ethoxylates, amine oxides)	0–trace	0.3–5
Bleach (sodium perborate, sodium percarbonate, hydrogen peroxide)	3–15	3–4 *
Fillers (sodium sulfate, sodium chloride)	5–20	0–2

Enzymes	0–1	–
Dyes, fragrances, pH-regulators	+	+
Water	balance	balance

* Hydrogen peroxide.

Table 33. Frame formulations of laundry boosters in the USA

Ingredients	Composition, %	
	Powders	Liquids
Builders		
Sodium carbonate	30–40	–
Sodium borate	0–50	0–1
Sodium silicate	0–5	–
Anionic surfactants (alkylbenzenesulfonates, alcohol sulfates, alcohol ether sulfates)	0–10	0–5
Nonionic surfactants (alcohol ethoxylates, amine oxides)	–	0–1
Hydrotropes	–	+
Fluorescent whitening agents	0–1	0–0.5
Enzymes	0–2	0–1
Dyes, fragrances, neutralizing agents	+	+
Water	balance	balance

Laundry boosters are marketed largely in the USA; various formulations exist. They contain either sodium silicate, sodium citrate, sodium borate, or sodium carbonate, usually in combination with surfactants. Enzymes are often present as well (Table 33).

4.3.3. Aftertreatment Aids

After the washing process has been completed and soil removal has been accomplished, fabrics are sometimes subjected to some type of aftertreatment. The goal is to increase the usefulness of laundry by restoring textile characteristics that have suffered in the course of the wash. Needs in this respect can vary considerably, depending on the fabric involved. Thus, products in this category may be called on to provide elastic stiffness, improved fit and body (shirts and blouses); smoothness, sheen; good drape (curtains); fluffiness and softness (underwear, towels, bath gowns); or antistatic properties (garments, underwear, hosiery, and other easy-care articles made from synthetic fibers). To achieve such effects, the following product groups are marketed:

Fabric softeners
Stiffeners
Laundry dryer aids

4.3.3.1. Fabric Softeners

Textiles washed by machine are subjected to greater mechanical stress than those washed by hand. Indeed, machine-washed laundry may be so severely jammed that the pile of the fibers at the fabric surface is reduced to an extreme state of disarray, especially in the case of natural fibers such as cotton and wool. During subsequent drying in static air (e.g., when laundry is dried hanging indoors), this condition tends to become fixed in the fabrics, and the laundry acquires a harsh feel. Addition of a liquid fabric softener in the final rinse (rinse-cycle softener) results in fabrics that feel softer.

The conditions described above are frequently found in Europe, Japan, and other regions of the world. Fabric softeners play another role in the USA, where laundry is mostly dried in mechanical dryers. The tumbling of the laundry in the dryer accomplishes its own softening effect. The chief task of household fabric softeners in the USA is rather to impart antistatic properties and a pleasant odor to the laundry. Therefore,

Table 34. Sorption of distearyldimethylammonium chloride * [147]

Textiles	Adsorbed amount **			
	mg/g	mol/g	mg/m^2	%
Wool	1.20	2.06	301	100
Resin-finished cotton	1.18	2.01	133	98
Cotton	1.17	2.00	169	96
Polyester/cotton	1.17	2.00	110	98
Polyamide	0.96	1.63	66	79
Polyacrylonitrile	0.90	1.53	68	74
Polyester	0.57	0.97	109	47

* Equilibrium conditions: time = 60 min, t = 23 °C, bath ratio = 1 : 10; initial concentration: 120 mg/L.
** Based on the mass and geometric surface of the textiles.

fabric softeners in the USA are frequently applied as sheets impregnated with active material which are added to the moist laundry at the beginning of the dryer cycle (see Section 4.3.3.3)

The principal active ingredients in commercially available rinse-cycle softeners are usually cationic surfactants of the quaternary ammonium type [149 – 152, 244, 245]. When applied in appropriate concentrations, cationic surfactants are adsorbed nearly quantitatively onto natural fibers, in contrast to their behavior with synthetic fibers (Table 34) [221 – 223].

To prevent undesired interactions between the anionic surfactants of a detergent and the cationic surfactants of a fabric softener, the latter must be introduced only in the last rinse cycle. Overuse of fabric softener must be avoided. Otherwise, the absorbency characteristics of the textiles decrease which in turn adversely affects the function of towels.

Conventional softeners, which contain on average 4–8 % active material, have been partially replaced in many countries by softener concentrates having some 12–30 % active material. This development is an answer to the increasing public environmental criticism centered on the bulky plastic packaging of conventional softeners. Bottles with volumes of 4–6 L of conventional fabric softener need large amounts of plastic for their manufacture, and also present waste disposal problems.

Due to its poor biodegradability the formerly widespread distearyldimethylammonium chloride (DSDMAC) [149], the former active material of most softeners in Europe, the USA, and Japan, has been replaced by the readily biodegradable (see Section 10.5.1) esterquats in the 1980s and 1990s. Frame formulations of liquid fabric softeners are given in Table 35.

The formulation of products with higher amounts of active material requires a well-balanced system of selected emulsifiers to maintain good dispersion stability upon storage.

Fabric softeners have additional benefits. They impart good antistatic properties on fabrics. They prevent the build-up of electrostatic charges on synthetic fibers, which in turn eliminates such unpleasant phenomena as fabric cling during handling and wearing, crackling noises, and dust attraction. Also, fabric softeners make fabrics easier to iron and help reduce wrinkles in garments. In addition, they reduce drying times so that energy is saved when softened laundry is tumble-dried. Last but not least, they also impart a pleasant fragrance to the laundry. That is why branded softeners are frequently offered with different fragrances.

4.3.3.2. Stiffeners

If stiffness and body are desired rather than soft and fluffy laundry, stiffeners can be added as aftertreatment. Usual agents for this purpose include natural starch derived from rice, corn, or potato, which can be used to impart extreme stiffness to fabrics. Synthetic polymeric stiffeners are good alternatives. They impart a more modest degree of stiffness than natural starch does, which is more closely attuned to contemporary taste. Products of the latter type are generally liquid and are easier to apply than natural starch. Stiffeners are supplied as dispersions and contain, in addition to a small amount of starch, substances such as poly(vinyl acetate), which has been partially hydrolyzed to poly(vinyl alcohol). Table 36 shows a frame formulation for typical European liquid stiffeners. Such products are offered not only as dispersions, but also

[a] Esterquat type: triethanol amine, diethanol amine, or epichlorohydrine esterified with tallow-based acids or oil-based acids are preferred in Europe. Diesters are preferred due to superior softening performance. Aside from esterquats, distearyl dimethyl ammonium chloride (DSDMAC) types, imidazolines, and amino ester salts are used in some countries.
[b] Fatty alcohols, fatty acids, triglycerides.
[c] Silicone oils, dispersed polyethylene.
[d] Magnesium chloride, calcium chloride, sodium chloride, sodium acetate.

as aerosol sprays. The latter allow local treatment of garments, for example, collars and cuffs.

Table 36. Formulation of liquid stiffeners in Europe

Ingredients	Composition, %
Alkyl/alkylaryl polyglycol ethers	0.1–2
Poly(vinyl acetates) (partially hydrolized)	10–30
Starch	0–10
Poly(ethylene glycols)	0.5–1.5
Fluorescent whitening agents	+/-
Dyes	+/-
Water	balance

Synthetic polymeric stiffening agents are called permanent stiffeners because, unlike starch, their effectiveness endures through several wash cycles. This property also has its negative aspects, however, since poly(vinyl acetate) film on a fabric can attract both soil and dyes, thereby leading to discoloration.

4.3.3.3. Laundry Dryer Aids

Laundry dryers are far more widespread in the USA than in Europe. They have held a significant place in the U.S. market since the early 1970s. Dryer aids are introduced into the dryer along with the damp, spin-dried laundry. During the drying process, they impart to the laundry both softness and a pleasant odor. Most importantly, however, they prevent static buildup on the fabric. The latter point is particularly significant in the USA, where synthetic fabrics are quite frequently used. Synthetic fabrics are less popular in Europe and elsewhere.

Laundry dryer aids are almost exclusively applied as sheets, which serve as carrier. The sheets are made from nonwoven material and impregnated with both fabric softeners and temperature-resistant fragrance oils. During the drying process, active ingredients from the dryer sheet are transferred to the laundry through frictional contact. The sheet materials are designed for single use and are discarded at the end of the drying cycle.

An additional reason for the popularity of dryer aids in the USA is the fact that washing machines in the USA often lack dispensers for automatic addition of liquid fabric softeners to the rinse cycle.

4.3.4. Other Laundry Aids

4.3.4.1. Refreshing Products for Dryer Application

Refreshing products form a new subsector in the laundry aids category. They were introduced in the USA and Europe in the late 1990s. These products are used for dry-clean and handwashable clothes. They do not replace professional dry cleaning, but they allow the consumers to refresh their garments any time at home. The custom products have two main features: a refreshing and a spot-cleaning action. The refreshing action is achieved inside the tumble dryer by using a moist impregnated sheet along with the item to be treated. Some systems use a plastic bag for producing a damp microclimate inside the dryer, whereas other systems work without a bag. In both cases the water vapor removes unpleasant odors from the garments. For spot cleaning either the moist sheet or a separate stain remover liquid is used in conjunction with an absorbent layer of cloth or paper placed underneath the stained garment to pick up dissolved soil.

4.3.4.2. Odor Removers for Washer Application

Laundry odor removers are liquid products. They were introduced on the U.S. market in the year 2000. Their formulation and technology allows the removal of (unpleasant) odors from laundry. The product is dispensed directly into the washer along with the detergent at the beginning of the wash cycle. Their main active component is based on cyclodextrins.

5. Industrial and Institutional Detergents

Even though the principles that determine the effectiveness of detergents for household and professional laundries are the same, detergents for large-scale institutional use generally differ insofar as they must be designed to meet the special circumstances associated with laundry on an industrial scale [224]. In contrary to home laundering, professional laundries have to deal with large volumes of textile garments and require therefore completely automatic processing with microprocessor-controlled machines and dosing units. They also need data retrieval systems for complete process control. The washing process is in general much shorter and is operated with soft water. For environmental and economic reasons energy and water recycling is essential. Since soil levels are commonly much higher in professional than in household laundry and the variety of textiles is very large, concentrated products, special bleaches, and stain-removal processes are often applied. In many cases disinfection of the laundry load is necessary. Specific packaging for laundry products in large quantities and safe storage systems are frequently required. On the whole, a professional laundry process is a thorough balance between economy, ecology, quality, and safety.

A large variety of products for professional laundries is available today. These products belong to one of the following three major categories:

Base detergents
Detergent additives
Specialty detergents

Table 37 shows the formulation of these products for institutional use.

Base Detergents. In principle, such products are completely built detergents and they are primarily responsible for a good basic detergency. Base detergents are usually highly alkaline and contain no bleach. The major ingredients are surfactants, builders (either phosphate or zeolite with polymer cobuilder), alkalies, fluorescent whitening agents, complexing agents, antiredeposition agents, and enzymes. Currently, they are used quite commonly in continuous batch washing machines with counterflow systems. Oxygen or chlorine bleach can be added depending on the degree of soiling. The addition of other detergent additives such as disinfecting agents or enzyme boosters is optional. Base detergents are available in form of powders, liquids, and pastes.

Detergent Additives. In order to improve the removal of heavy soilings and tough stains, which are quite common in professional laundries, detergent additives are frequently used. Special products like surfactant,

Table 37. Formulations of various types of detergents for institutional use

Components	Detergents		Partially built products		
	Base	Specialty	Surfactant boosters	Bleaching agents	Enzyme boosters
Surfactants	×	×	×		×
Sodium triphosphate or zeolite/polycarboxylate	×	×			
Alkalies (soda ash, metasilicate)	×	×	×		
Bleaching agents				×	
Fluorescent whitening agents	×		×	×	
Enzymes	×	×			
Complexing agents (phosphonates)	×			×	
Antiredeposition agents	×	×			×

alkaline, bleach, and enzyme boosters are commonly available. One of the most important additives is the disinfectant for hospital use. Such disinfectant additives are specifically designed to handle laundry originating from isolation wards and therefore require thermal and chemothermal sterilization. Common disinfectants for this purpose include peracetic acid–hydrogen peroxide mixture, sodium *N*-chloro-*p*-toluenesulfonamide (chloramine T), dichlorodimethylhydantoin, quaternary ammonium compounds, and other organic chlorine carriers which liberate active chlorine in the presence of water. Disinfecting procedures of this kind are mainly common in Europe. Laundry sterilization in the USA is accomplished either thermally or by active chlorine bleaches.

Table 38. Formulation of a perborate-containing detergent for institutional use

Components	Examples	Composition, %
Surfactants	alkylbenzenesulfonates, soaps, alcohol ethoxylates	10–15
Sequestering agents	pentasodium triphosphate, zeolite, polymer cobuilder	20–30
Alkalies	sodium carbonate/silicates	10–20
Bleaching agents	sodium perborate, TAED	15–30
Fluorescent whitening agents	stilbene derivatives	0.1–0.3
Antiredeposition agents	carboxymethyl cellulose, polymers	0.5–2
Corrosion inhibitors	sodium silicate	3–5
Foam iregulators	silicone/paraffin	0.1–0.3
Stabilizers	phosphonates	0.2–2
Fragrance oils		0.1–0.2
Enzymes	protease, amylase	0.5–1.0

Specialty detergents are products formulated in such a way as to meet the demands of particular kinds of laundry or particular laundering processes. These include, for example, detergents without whitening agents for easy-care and colored fabrics, detergents with high contents of nonionics for heavily soiled working clothes, and enzyme-containing products for proteinaceous soils.

In many semiprofessional laundries like in small hotels and restaurants, detergents which are more or less comparable to those for the household sector are required. For example, perborate-containing detergents have been very popular especially in Europe. The formulation of a perborate containing detergent is given in Table 38.

6. Production of Powder Detergents

Until 1987 the term powder detergent worldwide was synonymous to what today is called a conventional detergent. Powder detergents were manufactured mainly by hot spray drying and had densities of some 300 to 550 g/L. Triggered by the rapid market growth of compact detergents in Japan in the late 1980s, a significant change of the technology to manufacture high-density (> 600 g/L) heavy-duty detergents also took place in Europe and the USA, following the fast growing demands of the respective markets. In major parts of Europe and the vast majority of the USA, compact detergents became state of the art during the 1990s. In addition, detergent tablets have made their way in Europe since 1998, whereas their market introduction in North America began in 2000.

For compact powder detergents, the traditional manufacturing process comprising slurry drying of most detergent components in a spray

tower and postaddition of temperature-sensitive components had to be extended by an additional densifying step.

Figure 101. Manufacturing of compact powder detergents, schematic block flow diagram

In addition, quite a different development took place in the 1990s, namely, the use of nontower technology. This technology encompasses processes in which the drying step in the spray tower is replaced by a process which uses an increased number of dried raw materials and compounds (e.g., FAS on zeolite) than before. Initially, the bulk density of the tower powder was increased by dry mixing/milling the powder in fast-revolving, continuous, preferably high-speed mixers. In the 1990s, the European detergent industry developed new and more effective densifying processes which are based on tower powder, nontower granules, and dried raw materials or compounds. The achievable bulk densities depend on the detergent composition and the densifying process used (see Table 39).

Table 39. Densifying processes

Densifying process	Bulk density
Dry mixing/milling	650–720 g/L
Wet granulation/drying	750–900 g/L
Nonionic granulation	≈ 800 g/L
Roller compaction/milling	700–900 g/L
Bar extrusion/milling	700–900 g/L
"Spaghetti" extrusion	700–900 g/L
Tableting	> 1200 g/L

For each process many variants exist, e.g., wet granulation using

Water
Water-based binder, or
Pastes (surfactants)

in a

Dryer (fluidized-bed, linear, or round)
Mixer (Lödige, Fukae, Drais, Ballestra, Eirich, Schugi) [246], or
Combination of various mixers/dryers

A different technology has gained increasing importance as well, i.e., the process of mixing of compounds (see Section 6.2.4). In this process each raw material or part of it is separately agglomerated to dense particles. Therefore, anionic surfactant compounds, nonionic surfactants, builders, etc., can be easily varied in their content by dosing more or less of each compound. Compounds are manufactured by the detergent industry and — increasingly — by raw material suppliers, e.g., defoamer or tetraacetylethylenediamine granulates.

6.1. Technology Overview

Figure 101 depicts currently used detergent production technologies in a simplified way. Table 40 illustrates the main process alternatives, starting with drying/mixing, followed by a densification/shaping step. The processes are terminated with postaddition of thermally and chemically sensitive raw materials. Figure 102 additionally shows these alternatives as a chain.

Figure 102. Chains of different processes

Table 40. Detergents manufacturing process alternatives

Process	Drying step	Densifying step
Tower process	Spray drying	Dry mixing/milling

Nontower (mixer(s))-process	– fluidized bed

		  – extruded
		  – tableted
		  – roller compacted

Combination of tower/nontower "premix-process"	– one part is spray dried
	– another part is granulated with water and/or surfactants
	– third part is dry mixed
		– without densifying
		– integrated in the high shear granulation step, or
		– mixture is
		  – extruded
		  – tableted
		  – roller compacted

Compound process (mixer(s))	Compounds are – fluidized bed dried – roller compacted – granulated with surfactants	– integrated in the high shear granulation/extrusion/roller compaction step

6.2. Manufacturing Processes

6.2.1. Traditional Spray-Drying Process [247]

In the first step of the traditional spray-drying process (Fig. 103) a slurry of thermally stable and chemically compatible ingredients of the detergent is prepared. Solid and liquid raw materials are drawn off from silos or tanks and introduced batchwise into scales. Water is added as required to maintain a manageable viscosity. The liquid mixture and the solids are taken from the scales and mixed to form a slurry in a crutcher or by using some other type of forced mixer. The slurry is transferred to a stirred storage vessel from where the process runs continuously.

The slurry is transported by a low- or medium-pressure pump (up to 80 bar). Changes in pressure in the high-pressure portions of the system are compensated for by using an air vessel. The slurry is sprayed into the tower by two spraying levels connecting a series of nozzles. The number and type of nozzles must be designed such that overlapping of spray cones is avoided. Dried tower powder flows off from the tower at a temperature of 90–100 °C. To prevent lumping, an airlift is used for cooling.

The spray-drying process can be run cocurrently or, most common, countercurrently [248]. If particles and air move cocurrently and the slurry enters the hottest zone of the tower, a rapid evaporation of water occurs, and blown-up, relatively light particles (beads) result. In the countercurrent process, drying starts in an area of high humidity and lower temperature, and beads are obtained that are characterized by thicker walls. The lower free-fall speed due to the countercurrent airstream results in a higher number of particles in the tower at any time. Agglomeration products resulting from a countercurrent system are heavier and coarser than

Figure 103. Traditional spray-drying process

those resulting from cocurrent spray drying. Figure 103 shows a countercurrent operation. The air is directly heated by exhaust gases from an oil- or gas-fueled burner and led into the tower at about 300 °C through a ring channel. Appropriate design of both the air inlet zone above the cone and the air outlet at the tower dome is important. Air entering the tower is "swirled", i.e., it is accelerated tangentially and vertically. This causes homogeneous heat transfer between air and product. Water vapor, combustion gases, and drying air are withdrawn from the tower by means of a ventilating fan.

Fine particles are drawn off from the tower along with the exhaust gas and collected in a filter. In modern plants this filter is installed on top of the tower so that the separated fines and dust fall down into the agglomeration zone of the tower [249]. The resulting tower powder has a low content of fine particles. Heat exchangers are installed to use the exhaust gas energy for preheating the burner air. Another way is partially recycling the exhaust air (about 50 %) and mixing it with fresh air from the atmosphere [250]. In doing so, energy savings of about 10–20 % can be achieved. Plant control is possible by installation of an expert system [251].

6.2.2. Superheated Steam Drying

Environmental issues of spray drying using hot air are:

Emission of dust, normally < 10 mg/m^3
Emission of odor and volatile organic matter in very small amounts, normally < 50 mg/m^3
Potential dust-explosion and fire hazard
Loss of vaporization heat

These problems can be solved by switching over to drying with superheated steam instead of air [252]. The usage of superheated steam allows the heat of vaporization to be recovered [253]; the system is closed and no exhaust gas escapes from the tower [254]. Presently, this technology is being adapted in a pilot project [255].

The bulk density of steam-dried products is significantly higher and the water content is lower compared to hot-air spray drying.

6.2.3. Nontower Agglomeration Process

The nontower agglomeration process is carried out in a continuous mixer such as the Ballestra Kettemix Reactor or the Lödige CB-Mixer or in a combination of high- and low-shear mixers. Zeolite is applied in powdered form to bind surplus water, especially as zeolite P or X or as superdried zeolite A plus soda ash. In the first step the powder components are continuously added. Metering is carefully controlled at the entrance of the reactor. In this zone all liquids, such as nonionic surfactants, polymer solutions, fatty acids, sodium silicates, and linear alkylbenzenesulfonic acid, are separately dosed [256].

Due to the high energy input granules are formed and at the same time neutralization with sodium carbonate or sodium hydroxide takes place. The granules can take up limited amounts of nonionic surfactants. Optionally the granules are surface-treated with zeolite ("powdered") in an additional step to reduce product stickiness, which is mainly due to the nonionics. If the water binding capacity of zeolite and soda ash is not sufficient, e.g., in the case of neutralization with sodium hydroxide solution, added water and reaction water have to be removed from the product in a further step. This is done in a fluidized-bed dryer, where the granules are dried with hot air (140 °C) in the entrance zone. In the outlet zone the granules are cooled down, normally using cold air (5–15 °C). The drying process is controlled by measuring the product water content and temperature. Depending on the formula the product temperature has to be maintained between 50 and 110 °C (preferably between 60 and 80 °C).

If the water balance is fitted by using small amounts of water and/or by neutralization with carbonates the granules are only cooled in the fluidized bed and not dried. The fluidization air is transported in a cycle with a cooling/heating step to ensure a constant water content of the air.

After sieving and milling, the granules are transported to the postaddition step.

Figure 104. Nontower agglomeration process

Figure 105. Flow sheet diagram of a typical two-mixer nontower process

Quite a few limitations with respect to the nontower agglomeration process exist. Firstly, the neutralization heat increases the granulation temperature. Therefore, the amount of acids in the feed material is strongly limited. Secondly, the water level must be lower than 14 %. The nonionic surfactant content depends on the detergent composition. At higher nonionics contents the granules become too soft and

Figure 106. Dosing and mixing of different compounds

sticky. A typical nontower agglomeration process with one mixer and a fluidized-bed dryer is shown in Figure 104 as a block diagram. The more advanced variant with two mixers and a fluidized-bed cooler is illustrated in Figure 105 as flow sheet diagram. The process uses a high-shear/low-shear mixer combination. Neutralization is effected by using 50 % caustic soda.

6.2.4. Nontower Compound Technology

Another way of realizing a nontower process is application of compound technology. A finished laundry detergent is produced by blending the following components [257]:

Nonionic surfactant agglomerate	13.4 wt %
Anionic surfactant agglomerate	32.5 wt %
Layered silicate compacted granules	10.1 wt %
Granular percarbonate	22.7 wt %
Tetraacetylethylenediamine agglomerate	7.8 wt %
Suds suppressor agglomerate	6.5 wt %
Perfume encapsulate	0.1 wt %
Granular soil release polymer	0.4 wt %
Granular sodium citrate dihydrate	3.5 wt %
Enzymes	2.0 wt %

Each component is produced separately, in most cases by using the granulation technology. By applying different densification technologies an inhomogeneous product aspect results after blending of the compounds. Compound blending is presented in Figure 106.

6.3. Densification Processes

To increase the bulk density of the final product to values higher than about 650 g/L, one or more densifying steps must be used in detergent production and/or denser raw materials/compounds have to be applied. Usually, the particle size distribution of the densified product is adjusted by sieving/milling. In most cases the size distribution is similar to that of tower powder or standard products (0.2–0.8 mm). Larger and denser particles may retard dissolution of the finished product. Therefore, detergent manufacturers try to minimize the quantity of oversize particles.

Many process alternatives for densification exist. Typical process technologies are described in the following.

6.3.1. Dry Densification in a Mixer

A very simple and cheap method for achieving a limited increase in detergent density is mixing/milling/spheronizing of tower powder in a continuous mixer such as the Lödige CB-mixer (Fig. 107). The densification yields an increase in bulk density of 50–100 g/L [258, 259]. Usually, a liquid (nonionic surfactant) is added to the CB-mixer to reduce stickiness, especially at the mixer walls and the tools.

Figure 107. Lödige CB-mixer for dry densification of detergent tower powder (view of the internals)

6.3.2. Dry Densification in a Spheronizer

The bulk density of some products can be increased slightly by rounding off the particles in a spheronizer [247]. After entering the spheronizer the particles are accelerated by a high-speed rotating disk. They are driven against the vessel wall by centrifugal forces. There they roll against each other in a particle cloud. As a consequence, edges and surfaces of the particles are polished. In this way, the form of the particles is improved.

6.3.3. Dry Densification in a Roller Press

Compacting of raw materials or compounds in a roller press is a very simple process, that is followed by a relatively complex milling/sieving step (Fig. 108). Compacting in a roller press is accompanied by a dust problem, especially when using products with a high content of organic matter. The resulting product is very dense, but the particles are irregular in shape (splinters). The latest development in this field is a closed device in which rolls, mills, sieves, and recycling tubes are installed in one unit.

For "dry" densification an extruder can be applied as well. In this case, a binder/lubricant must be added to the powder mixture. The product is extruded to form bars. The final form can be achieved by milling/sieving, as shown in Figure 108.

a) Original powder feeder (lower hopper), b) Recycle system, c) Upper feed hopper, d) Horizontal feed screw, e) Vertical screw, f) Compaction rolls, g) Pressure applied, h) Prebreak, i) Granulator, j) Screen, k) Screener

6.3.4. Wet Granulation

Wet granulation is the most common process for densifying tower powders, raw materials, or compounds. Wet granulation is performed by adding water, polymer solutions, anionic surfactant pastes, or surfactant gels at high shear rates [260 – 263]. The wet granulation process consists of the following steps:

Step 1: grinding in a high-speed mixer or in a mill; addition of polymer solution (7–12 %) via spray nozzles to the powder in the mixer (pregranulation)

Figure 109. Flow sheet of a typical nontower granulation process

Step 2: granulation and conditioning in a high- or medium-shear-rate mixer
Step 3: evaporation of added water in a fluidized bed and/or cooling down
Step 4: sieving of coarse particles and milling; usually, fine particles remain in the product

Figure 109 illustrates one of several possible designs of a typical wet granulation process [264]. The use of two or more mixers of different types in a cascade increases process flexibility. Energy input, granulation temperature and time, dosage of liquids, powdering of the particles, and types of mixers represent the know-how of the detergent manufacturers.

A very promising new granulation technology is foam granulation [265, 330]. Usually, the granulation liquid is sprayed on the solids or dosed in a jet. The addition of a foam enables a more flexible granulation with less recycled material. A comparison of different granulation techniques is shown in Figure 110.

Figure 110. Wet granulation

6.3.5. Spaghetti Extrusion

The spaghetti extrusion process represent a new approach to densifying detergents. Powders, raw materials, and compounds are mixed while a lubricant is added. The mixture is plastified in an extruder and pressed through many small holes. The resulting spaghetti-shaped detergent strands are cut in such a way that the length-to-diameter ratio of the resulting tiny cylinders is unity. The cylinders are rounded off in a spheronizer [227,

Figure 111. Flow sheet diagram of the extrusion ("Megaperls") process

266]. To harden the product an additional cooling step can be necessary. This densification process has the advantage that a dust-free product is obtained with spherically shaped particles of uniform size, whereas all other processes deliver powders, granulates, splinters, or mixtures thereof, that have a more or less broad spectrum of particle sizes.

Densification by extrusion occurs before the postaddition process (Fig. 111). If the raw materials are used as they are, no further granulation step (e.g., tower drying or wet granulation) is necessary. Both densification and particle shaping occurs inside the extruder by means of a specially constructed extruder head and knife.

The detergent mass is plastified in a cooled twin-screw extruder. In the extruder head a mass temperature of 60 to 80 °C prevails under a pressure of 70 to 110 bar. The mass is pressed through bore holes of 1.4 mm in diameter. There are about one hundred bore holes per plate and more than hundred plates per extrusion die.

The extruded particles differ significantly from other detergent particles, they are much larger, spherical, and nearly uniform (see Fig. 112).

Figure 112. Appearance of market detergent products
A) Particles from granulation/compounding; B) Particles from extrusion

6.3.6. Postaddition Process

The finishing process of granulated or extruded detergents includes postaddition of thermally sensitive raw materials and/or chemically incompatible ingredients such as bleaching components (sodium perborate, sodium percarbonate), bleach activators, enzymes, soil repellents, foam inhibitor concentrate, fragrances, and, occasionally, colored granules. After the postaddition step the finished product is ready for sieving and packaging.

Postadded granules or powders generally have to be adjusted in their particle size distribution to match the particles of the base powder. Smaller postadded particles, particularly when they have higher densities, tend to segregate in the package or in the process before.

6.3.7. Dry Densification in a Tablet Press

Tablets are a convenient application form for laundry products. Tablets may consist of one, two, or more layers. In Europe, usually two tablets are recommended to clean a 4.5 kg laundry load in the washing machine. To achieve maximum performance all ingredients need to be in a dissolved state from the very beginning of the wash cycle [267 – 271]. Two main problems must be solved:

1) The low surface-to-volume ratio of detergent tablets adversely affects the dissolution rate.
2) In the presence of surfactants, especially nonionics, gel phases may form upon first contact of the tablets with water. Gel formation impedes fast dissolution.

The different concepts that have been developed to formulate and to produce tablets that quickly disintegrate are presented in Section 4.1.4.

Independent of the product concept many physical parameters are identical for the finished tablet and its manufacturing (Table 41). All manufacturers use rotary die presses for production.

The critical points of tableting detergents are the strong reciprocal dependency of tablet hardness and dissolution or disintegration time. The tableting pressure depends on the mechanical stability of the tablet and on its disintegration time. Tablets produced under high pressure are very stable but have too long disintegration times. On the other hand, tablets produced under low pressure are friable. Only a narrow range of tableting pressures can be applied for producing stable, nonfriable tablets with a short disintegration time. The so-called operation area for the tableting press is not fixed, the values depend on formula, size and distribution of the particles as well as on the bulk density of the premixture.

Table 41. Parameters affecting tablet quality and process efficiency

Product Assumptions	Process Conditions	Tableting Machine Arrangement
• Formula (formula splitting into two phases) • Content of liquids • Tableting aids • Particle size and distribution • Bulk density • Stickiness • Particle shape • Moisture content • Disintegrant in the tablet and/or coating	• Speed of tableting • Climatic conditions • Hardness of particles and tablets • Homogeneity of mixtures • Compressibility • Pressure of tableting • Temperature of the tablets	• Surface of the punches • Dosing systems • Tablet shape, weight, height and type • Control systems • One, two or three different phases • Tablets with an inscription

As described in Section 6.3.6, the particle size distribution of all formula components has to be adjusted.

The ingredients of the tablet can be separated into two layers. In this way, for example, enzymes and bleach can be compacted together in one tablet but in different layers without interaction during storage. The manufacturing process for a single-layer tablet is given below. For the second and third layer, the same procedure is applied in separate equipments to components with different composition and color:

Step 1: Granulation of the main components and drying
Step 2: Sieving of the granules in a range of 0.2 to 2 mm or a smaller range
Step 3: Postaddition/mixing/sieving (bleach, enzymes, salts, optical brighteners, polymer compounds, fragrances, suds and pH regulators, recycled materials, dyes)
Step 4: Tableting
Step 5: Flow wrapping of the tablets
Step 6: Packaging

The whole process must be temperature- and moisture-controlled. To prevent picking and sticking of granules the water content is limited to 6–9 %, depending on the formula. To ensure maximum action of the disintegrant, wrapping of the tablet in a so-called flow packer is necessary. Each flow pack usually contains two tablets for one wash cycle.

Figure 113 shows the dependency of the tableting pressure and dissolution rate on the particle size. Very fine particles need low pressures to form stable tablets. Since a disintegration agent with a small particle size develops only low forces, a minimum size of the disintegrant is needed, optimally adjusted to the particle size distribution of the granules. An interesting range of particle size may be, for example, 0.4 to 1.2 mm.

Figure 113. Dependence of the tableting pressure and dissolution rate on the particle size

Figure 114. Punches of a double-layer tableting machine [272]

A contrary approach is the manufacturing of a friable, unstable detergent tablet with low tableting pressures. This kind of tablets already break by simply touching them. To stabilize the product it has to be coated with materials that form a very hard, easily melting layer or shell. A preferred technology may be using an enrober with single or double curtains. Suitable raw materials for enrobers are C_{12-14} dicarboxylic acids combined with a disintegrant.

Rotary die presses are used for tableting detergents [246]. Two-layer-tablet presses are equipped with an upper and lower punch and two filling stations. The residence time under maximum pressure and the press forces determine tablet stability and disintegration time. Figure 114 shows the punches.

6.4. Raw Materials

Each of the key detergent ingredients (see Chap. 3) consists of chemically and physically very different raw materials, also called systems, e.g., bleaching systems with sodium perborate monohydrate or percarbonate and TAED. The ingredients influence the choice of production technology.

6.4.1. Anionic Surfactants

For laundry detergents usually linear alkylbenzenesulfonates and alcohol sulfates, linear or branched, are used as anionic surfactants. As LAS do not crystallize, they are only available on the market as an aqueous paste or a dusty powder or powder compound. Alcohol sulfates crystallize more or less well, depending on their carbon chain distribution. Quite a few manufacturing processes exist for the production of AS compounds with up to 93 % active matter. Anionic surfactants and their manufacturing processes are amply described in the literature [273].

The starting materials for alcohol sulfates, alcohol sulfuric acid semiesters, are derived from sulfation of long-chain alcohols (C_{12}–C_{18}) with SO_3. The semiesters are not stable and have to be instantaneously neutralized with sodium hydroxide. One process is "low-water" neutralization with highly concentrated sodium hydroxide at elevated temperatures in a melt in a continuous neutralization loop [274]. Another technology applies a spray neutralization process, in which the alcohol sulfuric acid semiester and sodium hydroxide solution are mixed and sprayed into the tower using a special nozzle. The heat of neutralization evaporates the water, so that no further energy input is required for drying [275].

Figure 115. Flow sheet of the one-step agglomeration/drying process[279]
a) Fluidized-bed dryer; b) Fluidized-bed cooler; c) Heater for process air; d) Deduster; e) Dosing pump; f) Metering rotary valve; g) Conveying air fan; h) Fan

The resulting powder must be granulated under densifying conditions [276]. Another method embodies drying in a high-shear-rate dryer, in which the paste is dried in a thin film along the wall of the dryer [277].

A further process recommends applying vacuum neutralization in a special film reactor with a high-shear mixer on the top [256]. The reaction rate is controlled by continuously measuring the pH value of the product. Alcohol sulfates are most frequently used in a paste delivery form. The paste can be dried in a cocurrent spray-drying tower under inert atmosphere. The resulting powder is very light and fine and must be densified, e.g., by extrusion as noodles. The produced shape is shown in Figure 116.

The Ballestra company offers the Dryex process for the production of dry anionic surfactants, especially for AS. The neutralized and preheated (80–85 °C) pastelike surfactant is fed into the top of a wiped film evaporator. Rotating blades form a thin film over the evaporator surface and remove the dried product from the wall. Drying is supported by using a slight underpressure. The product can be flaked and milled in-line. Similar processes are available from various manufacturers of thin-film evaporators.

In another more elegant and economic method the paste is dried in a fluidized-bed dryer/agglomerator. This process, shown in Figure 115, performs drying, densifying, and sieving in one apparatus [278]. The paste is sprayed onto smaller particles, for example, product dust which is fluidized in the bed. The product is sprayed and dried shell by shell. Rotation and the method of drying provide products of high bulk density. The stickiness can be reduced by compounding with carrier materials such as zeolite, starch, and inorganic or organic salts.

The drying of AS paste is accompanied by emissions resulting from unavoidable small amounts of free fatty alcohols in the exhaust air. The problem may be partially resolved by reducing the inlet temperature.

Shape and particle size of the product depend strongly on the process type, as shown in Figure 116.

Figure 116. Particle shapes of dried anionic surfactant salts

6.4.2. Nonionic Surfactants

Nonionic surfactants are derived either from natural renewable feedstocks or from petrochemicals. As *renewable raw materials* for surfactants, particularly tallow, coconut and palm kernel oil (laurics), and soybean oil are of paramount importance. The oils are purified in a first step with sulfuric acid in separators or decanters [43, 280]. The triglycerides are either split with steam at elevated temperatures and pressures to form fatty acids and glycerol, or transesterified with methanol to produce fatty acid methyl esters in a one-step reaction. The methyl ester are subsequently hydrogenated to form fatty alcohols (→ Fatty Alcohols).

For the production of fatty alcohols from *petrochemicals* (paraffins and ethylene) a range of processes exist [281]. The most well-known processes start with the catalyzed oligomerization of ethylene either according to the Shell Higher Olefins Process (SHOP; → Hydrocarbons, Section 2.1.2.2) or the Ziegler trialkylaluminum process (→ Alcohols, Aliphatic, Section 2.3.5). The SHOP olefins are hydroformylated with carbon monoxide and hydrogen to form aldehydes (→ Oxo Synthesis) and in a further step hydrogenated to low-branched alcohols (→ Alcohols, Aliphatic, Section 2.3.2). In the Ziegler process trialkylaluminum is oxygenated and in a further step hydrolyzed with sulfuric acid, which converts it to long-chain linear alcohols.

The manufacture of nonionic surfactants starts in most cases with chemical modifcation of fatty alcohols, fatty acids, or fatty acid methyl esters. Fatty alcohols are converted to alcohol ethoxylates and alkylpolyglycosides; fatty acids to fatty acid ethoxylates and alkanolamides; and the methyl esters to the corresponding ethoxylates and glucamides. Important nonionic surfactants are shown below:

Fatty alcohol ethoxylates $R–(OCH_2–CH_2)_nOH$

Fatty acid methylester ethoxylates

Fatty acid ethoxylates

N-Methylglucamide

Alkylpolyglycosides (APG)

$R = C_8–C_{18}$
$R_1 = C_7–C_{17}$
$n = 2–10$
$m = 1–3$

Ethoxylated fatty alcohols are the most important nonionic surfactants. Also, ethoxylated fatty acids and fatty acid methyl esters [266] are valuable products for the detergent industry. Therefore, ethoxylation is a key technology for manufacturing nonionic surfactants. The ethoxylation process is conducted in batch reactors. A description of the ethoxylation process in given in → Surfactants, Section 7.2.

The ethoxylated substrates are chemically inhomogeneous because, firstly, the raw material has a chain length distribution (e.g., $C_{12}–C_{14}$ alcohols) and, secondly, the addition of ethylene oxide is carried out in a broad concentration range. The designation "fatty alcohol + 7 EO"

indicates a mean value of seven added molecules of ethylene oxide per molecule of alcohol. In reality a mixture of alcohol ethoxylates with zero to eighteen EO moieties (broad-range ethoxylates with KOH catalyst) is obtained. When special catalysts are used, narrow-range ethoxylates are formed. These process parameters affect the product quality significantly and are part of the manufacturer's know-how.

6.4.3. Builders

Quite a few builders are applied in the detergent industry today. Worldwide, sodium triphosphate is a key builder used on a large scale. Since the early 1980s sodium aluminum silicates (zeolites) have become more and more important, particularly in Europe, the USA, and Japan. Today, the field of builders/cobuilders is more complex than ever. Apart from sodium triphosphate and zeolites, special layered silicates, amorphous silicates, and compounds made from sodium carbonate and amorphous silicate are applied [169, 170, 282]. Besides zeolite A, other zeolite types have gained importance, e.g., zeolite P and zeolite X. Production processes for zeolite A have been described [247].

Layered Silicates. Several methods have been established for manufacturing layered silicates. One method uses the crystallization of amorphous sodium silicates (SiO_2:Na_2O ratios from 1.9 to 3.5), evaporation of the water, and tempering at above 450 °C but below the melting point, to achieve complete crystallization. From this process α-, β-, γ-, and δ-silicate ($Na_2Si_2O_5$) modifications are available [169, 283, 284]. Another process comprises spray drying of a water glass solution, milling of the product, and tempering in a rotary kiln at 400 to 800 °C for 1 h to crystallize the sodium disilicate [285]. Subsequent densification can be carried out by roller compaction, if necessary.

Amorphous Silicates. A simpler process is the manufacture of amorphous silicates. A spray-dried silicate solution having an SiO_2 : Na_2O ratio of between 2 and 3.5, which is derived from the hydrothermal or water glass process, is compacted and partially loaded with a selected liquid, e.g., nonionics [286]. A variation of the densifying process is the granulation of milled silicate particles [274, 287].

In the 1990s, some raw material suppliers developed manufacturing processes for detergent-grade zeolite types, such as zeolite P and zeolite X, which feature increased loading capacity for liquids [256, 288 – 290]. The manufacturing processes differ from the zeolite A manufacturing technologies in the crystallization conditions.

6.4.4. Peroxygen Bleaches

The detergent industry has used sodium perborate tetrahydrate or monohydrate as a source of active oxygen since 1907. In addition, sodium percarbonate has gained increasing importance in the last decades.

Sodium Perborate. As raw materials for the sodium perborate tetrahydrate process boron minerals, e.g., kernite or tincal with B_2O_3 contents $> 47\,\%$, are utilized. In the first step the boron compounds are dissolved in an alkaline solution at about 90 °C to form sodium metaborate:

$$Na_2B_4O_7 + 2\,NaOH \rightarrow 4\,NaBO_2 + H_2O$$

After filtering and diluting the solution to 75 g/L, hydrogen peroxide is added with cooling (< 30 °C) in a crystallizer:

$$NaBO_2 + H_2O_2 + 3\,H_2O \rightarrow NaBO_3 \cdot 4H_2O$$

The sodium perborate tetrahydrate crystals are separated from the liquid phase in a centrifuge. They contain 3 to 10 % of surface-adsorbed water which is removed in a fluidized-bed dryer with product temperatures below 60 °C. Above this temperature (65.5 °C) the product melts in its water of crystallization. Sodium perborate monohydrate is produced from the tetrahydrate by dehydration in a fluidized bed, conditioning, and drying with a steam–air mixture at temperatures not exceeding 100 °C. In its crystalline state sodium perborate forms a stabilizing anion (see Section 3.3.1) [174, 291]:

Sodium percarbonate ($Na_2CO_3 \cdot 1.5\ H_2O_2$) is easily manufactured starting from a crystallization process or from spraying a 35 % aqueous hydrogen peroxide solution onto sodium carbonate in a mixer or, preferably, in a fluidized bed. Percarbonate stability depends on the degree of purity of the sodium carbonate used. Especially heavy metal ions adversely affect the stability by catalyzing the decomposition of hydrogen peroxide.

To enable storage of sodium percarbonate in silos it has to be protected by a coating layer. It is common to use inorganic materials as a coating layer, e.g., sodium carbonate, sodium perborate monohydrate, or sodium sulfate. Coating is performed in batchwise or continuously operating fluidized beds.

Stability. All bleaching agents mentioned above are storage stable up to 60 °C. The perborates are stable at this temperature even when they are loaded with nonionic surfactants. Dust and particles of percarbonate in direct contact with even small amounts of organic material may result in spontaneous ignition of the organic material. Caution measures are to be taken in case of a damaged coating layer or with broken particles.

6.4.5. Enzymes

Detergents may contain up to four different types of enzymes: proteases, amylases, cellulases, and lipases. Enzymes are effective at low temperatures. Even small amounts of these biocatalysts guarantee major effects.

Enzymes are produced in fermenters by microorganisms such as bacteria, yeasts, and fungi. For production of proteases and amylases *Bacillus* species are used, which today are usually genetically engineered. A flow sheet of production of enzymes for detergents is show in Figure 117. Production of enzymes is described in more detail in → Enzymes, Section 3.1.

Figure 117. Downstream processing in enzyme production

In the fermenter, the extracellularly produced enzymes are dissolved and highly diluted in the fermentation broth. The first step of downstream processing is the separation of the biomass and other solids originating from the nutrient medium (Fig. 117).

Three alternatives are in use:

Centrifuges with extreme centrifugal forces (separators)
Precipitation with salts
Microfiltration

This separation step has proved difficult in practice because the bacterial cells that produce the enzymes are very small (0.2 to 0.5 µm) and their density is close to that of the fermenter broth. Moreover, the fermenter broth has a relatively

Figure 118. Extrusion process [293]

high viscosity, frequently combined with a non-Newtonian flow behavior. A further limitation is imposed by the poor temperature stability of the enzymes, so that, in many cases, the working temperature may not exceed 30 °C [292]. In addition, slimes can impede work-up.

To guarantee a microorganism-free product, a sterile filtration in a microfiltration plant follows. In the next step the highly diluted solution is ultrafiltered to achieve 15- to 25-fold concentration of the large protein molecules. For the next step two alternatives exist:

1) Precipitation of the enzymes, filtering the suspension, washing and dissolution of the cake.
2) Deodorization of the concentrated enzyme solution to remove unpleasant odors, generated during fermentation and sterilization. This is conducted in vacuum with superheated steam.

The concentrated enzyme solution is finally sprayed on solid carriers, granulated or extruded (Fig. 118), dried, and coated. Coating is performed in a fluidized bed by spraying a polymer solution on the particles under drying conditions. The coating layer must be perfect to prevent human contact with the particles and to make them dust-free.

7. Analysis of the Composition

The fact that detergents can consist of a large number of individual components whose structures vary greatly is apparent from Chapters 3 and 4. The dramatic industrial advances of the past 50 years together with ecological and economic issues have resulted in steady modifications of detergent formulas. These modifications have required adjustments of analytical methods, with routine procedures frequently becoming outdated.

The multitude of products and a constantly growing variety of raw materials, as well as the complexity of their constitution, makes a summary of the methods used for detergent analysis difficult, especially because the situation is complicated even further by the wealth of analytical techniques available.

The most important factor in choosing an analytical method is the nature of the question posed. In addition, the value of an analysis is highly dependent on the use of proper sampling techniques. Often several methods of analysis are employed in the search for a single answer.

The following procedure can be regarded as a typical example of how a general analysis of a powder detergent might be conducted:

First, the product is separated by extraction into ethanol-soluble and ethanol-insoluble fractions. The ethanol extract can usually be regarded as containing all of the surfactants. The various surfactants are then determined: anionic surfactants by two-phase titration, nonionic surfactants by passing the ethanol extract through both anionic and cationic ion-exchange resins, and the soaps either by titration of the alkalinity of the ethanol extract or by a second two-phase titration in alkaline medium. After suitable sample preparation, such major inorganic components as carbonates, silicates, phosphates, borates, and sulfates are determined either instrumentally or by classical wet methods. All of the more specialized auxiliary ingredients (e.g., soil antiredeposition agents, fluorescent whitening agents, enzymes, chelating agents, bleach activators, etc.) are present in relatively small quantities, and their qualitative and quantitative analysis requires considerable knowledge and experience. Thus, they would fall outside the bounds of a general investigation.

Following is a summary of the literature on detergent analysis. This is intended only as a useful overview. The information has been divided into five categories:

1) Detergent ingredients
2) Purposes of detergent analysis
3) Importance of sample preparation
4) Analytical methods
5) Sources of information

7.1. Detergent Ingredients: [238 – 243, 294 – 298]

Inorganic components: [299 – 306]
Organic components: [307 – 312]

7.2. Purposes of Detergent Analysis: [313]

Raw material analysis (triphosphate and alkylbenzenesulfonate): [314 – 316]
Production control (EO products): [317]
Product quality control (detergent analysis): [318, 319]
Market analysis (detergents): [310], [311, pp. 991–1045], [320 – 325], [326, pp. 25–43 (1977)]
Trace analysis (vinyl chloride in PVC): [327 – 329]
Analysis of formulated products: [330]
Analysis of detergent formulation: [331]
Detergent analysis: [332]

7.3. Sample Preparation: [310, pp. 21–26]

Liquids, solutions, suspensions, emulsions, and pastes: [315, p. 6], [333, H–I 4 (65)]
Detergent bars: [333, G–I 1–3 (50)], [334, Da 1–45]
Powders: [333, H–I 5], [334, Dc 1–59, Dd 1–59], [335, ISO 607 (1980)], [336], [337, DIN 53 911]

7.4. Analytical Methods

7.4.1. Qualitative Analysis: [310, pp. 27–49], [322, pp. 166–178]

General Analysis:
Solubility, pH: [333, H–III 1 (65)]
Elemental analysis: [333, H–III 5 (65)]
Analysis for Inorganic Ingredients: [338, 339]
Active oxygen: [338, p. 171], [339, pp. 492–493]
Peroxide accumulation in detergents: [340]
Active chlorine: [338, p. 159], [341, Part 2, vol. VII, p. 35]
Ammonia: [338, p. 241], [342, E 5]
Boron: [338, p. 230], [339, p. 776],
Water-insoluble inorganic builders: [243, 343 – 347]
Analysis for Organic Ingredients: [348 – 350]
Alkanolamines after hydrolysis: [310, p. 32],[312, 351]
Sequestrants (NTA, EDTA): [352, 353]
Urea: [354], [355, p. 235], [356]
Fluorescent whitening agents: [310, p. 414], [357 – 359]
Anionic surfactants: [360 – 363]
Alkylene oxide adducts (EO, PO, aromatics): [310, p. 46], [348, p. 138], [362, 364, 365]
Hydrotropic substances: [354]
Enzymes: [366]
Carboxymethyl cellulose: [367 – 371]

Amphoteric surfactants: [372]
Alkyl polyglycosides: [373, 374]
Polycarboxylates: [375]

7.4.2. Sample Preparation

Extraction, Perforation, and Sublation
Ethanol solubles: [310, p. 148], [333, H–III 4 (65)]
Soap fatty acids: [333, G–III 6 b (57) and G–III 8 (61)], [376, p. 1352]
Monosulfonate in alkanesulfonate: [315, p. 39],[333,H–IV 2 b (76)], [335, ISO 3206 (1975)]
Acetone solubles: [310, pp. 253 and 362]
Nonionic surfactants in wastewater: [377]
Nonionic surfactants in sludge: [378]
Polyglycol in ethylene oxide adducts: [379]
Distillation: [380]
Ion Exchange: [310, pp. 50–58], [381]
Nonionic surfactants, anionic surfactants, cationic surfactants, soap, fatty acids, and urea: [382 – 389]
Antimicrobicides: [390]
Phosphate types: [310, p. 467]
Carbon Methods
Sulfate: [333,H–III 8 b (76)]
Phosphate: [391]
Decomposition Methods: [392]
Residue on ignition, with hydrofluoric acid digestion: [393, p. 8]
Sulfate ash: [310, p. 335], [333, H–III 11], [394]
Borate: [310, pp. 474–476]
Borate decomposition for X-ray fluorescence analysis: [316, 395, 396]
Potassium disulfate melt for Al and Fe: [393, p. 12]
Soda–potash decomposition for water glass: [393, p. 9]
Wet Decomposition
Sulfuric acid–nitric acid, perchloric acid, nitric acid–perchloric acid: [397, pp. 188–209]
Measurement of zeolite, silicate, and phosphate: [347]
Chemical Transformations: [398]
Sodium hydrogen sulfite–acid hydrolysis: [221, p. 152], [333, H–IV 7 a], [399], [376, pp. 1474 and 1353], [400, 401]
Cleavage of ether sulfates: [310, pp. 279 and 323], [402 – 404] [405 – 407]
Esterification of fatty acids: [310, p. 572], [408 – 411]
Desulfonation (alkylbenzenesulfonates, alkanesulfonates): [310, p. 197], [403, 404, 412 – 417]

Acetylation (fatty alcohols): [418, p. 543]
Determination of industrial grade carboxymethyl celluloses: [369]
Alkaline Hydrolysis: [310, p. 150]
UV photolysis: [419]

7.4.3. Quantitative Analysis

Gravimetric Analysis
Inorganic Ingredients
Dry residue: [310, p. 434], [420]
Carbon dioxide: [341, Part 3, vol. IV aα pp. 225–229]
Silicon dioxide: [407, D 501–558], [421], [310, p. 447], [341, Part 3, vol. IV aα, p. 456]
Phosphorus pentoxide: [310, p. 452], [335, ISO/ TC 91 444F], [341, Part 3, vol. V aβ, p. 118], [422]
Sulfate: [333, H–III 8 b (76)], [423]
Magnesium: [310, p. 492], [341, Part 3, vol. II a, pp. 141–149]
Organic Ingredients: [376]
Ethanol solubles: [310, p. 148], [333, H–III 4 (65)]
Loss on drying: [310, p. 548], [420]
Unsulfated fraction (US): [310, p. 555], [335, ISO–893 (78) and ISO–894 (77)]
Nonsaponifiable fraction: [310, p. 555], [333, C–III 1 a and 1 b (77)]
Soap fatty acids: [310, p. 550], [333, G–III 6 b (57) and G–III 8 (61)], [376, p. 1352]

Nonionic surfactants: [310, p. 167], [333, H–IV 9 b]
Volumetric Analysis: [310, p. 215], [424, 425]
Acidimetry
Alkalinity: [310, pp. 334 and 472]
Sodium oxide content in soaps: [310, p. 554], [333, H–III 7 a (65)], [426]
Borate: [310, p. 474], [341, Part 3, vol. III, pp. 11–60]
Potentiometry: [427 – 429]
Phosphate: [310, pp. 455 and 480]

Borate: [310, p. 480], [430]
Chloride: [310, p. 446], [341,Part 3, vol. VII aβ, pp. 107–109]
Fluoride: [431, 432]
Nonionic surfactants in wastewater: [377]
Nonionic surfactants in detergents: [433]
Ionic surfactants: [434 – 441]
Ethylenediaminetetraacetate: [442]
Complexometry: [443, 444]
Ethylenediaminetetraacetate: [310, pp. 403 and 487], [335, ISO TC 91/490]
Nitrilotriacetate: [310, p. 403], [335, ISO TC 91/513 E]
Citrate: [445]
Calcium: [342, E 3], [446, p. 25]
Magnesium: [443, pp. 136–137], [446, p. 28], [342, E 4]
Nonionic surfactants: [447]
Conductometry: [448]
Sulfate: [449]
Two-Phase Systems: [310, pp. 215 and 218], [320, p. 427], [315, p. 16], [450, p. 221]
Anionic surfactants: [310, p. 234], [333, H–III 10], [401, 451, 452]
Cationic surfactants: [335, ISO 2871 (73)], [453]
Turbidity titration: [454]
Miscellaneous Titrimetric Analyses:
Sulfate: [310, p. 442], [315, H–III 8 a (76)], [333, H–III 8 a (76), p. 24; H–III 8 d (76)], [455, 456]
Chloride: [310, p. 445], [341, Part 3, vol. VII a, pp. 98, 99]
Water by Karl Fischer method: [310, p. 435], [333, H–III 3 a (65)], [335, ISO 4317 (77)]
Active oxygen: [310, p. 483], [335, R 607], [341, Part 3, vol. VI aα, pp. 193–207]
Active chlorine: [310, p. 487], [341, Part 3, vol. VII aβ II, pp. 74–76]
Calcium and magnesium binding capacity: [457, 458]
Gluconate: [459]
Bleach activator: [460]
Spectrophotometric Determinations: [397]
Perborate: [461, A 124]
Phosphate: [310, p. 457], [422, 462 – 464]
Enzymes: [465 – 467]
Enzymatic analysis: [468, 469]
Alkylpolyglycosides: [470]
Polycarboxylates: [471]
Trace elements: [397]
Anionic surfactants in wastewater: [423, 472 – 474]
Cationic surfactants in wastewater: [475]
Size Exclusion Chromatography:
Polycarboxylates: [476]
Flame Photometry: [477]
Sodium and potassium: [477]
Atomic Absorption Spectrometry: [478 – 481]
Traces of Cu, Fe, Zn, and Mn: [482, 483]
Traces of As: [484]
Traces of Co: [485]
Atomic Emission Spectrometry: [344, 486]
X-Ray Fluorescence: [316, 487 – 490]
X-Ray Diffraction: [491]
Phosphate phases I and II: [492]
Zeolite types: [493]
Radiometric Methods: [494 – 496]

7.4.4. Separation Methods: [497], [498, p. 21]

Capillary Zone Electrophoresis:
Anionic surfactants: [499, 500]
Polycarboxylates: [501]
Paper Chromatography: [502]
Phosphate types: [310, p. 460], [314, 503]
Alkanolamines: [504]
Alkanolamides: [310, p. 391]
Urea: [497, pp. 360 and 402], [502, p. 210], [505]
Thin-Layer Chromatography: [310, p. 45], [350, 506, 507]
NTA, EDTA: [508]
Akanolamines: [312]
Ether sulfates: [509]
Surfactant mixtures: [362, 363], [450, p. 47], [510]
Free fatty alcohols in ethylene oxide adducts: [511, 512]
Bactericides: [390, 513]
Amphoteric surfactants: [310, p. 371], [514]
Anionic surfactants: [515 – 517]
Optical brighteners: [518]
Nonionic surfactants in wastewater: [519, 520]
Column Chromatography: [310, pp. 51–63], [498, 521, 522]
Glycerides [376, Part I, p. 832], [523]
Fatty acid polyglycol esters: [524]
Petroleum sulfonates: [310, p. 61], [525]

Nonionic surfactants: [310, p. 167], [526]
Gas Chromatography: [310, p. 80], [527 – 530]
Fatty acid carbon-chain distribution: [411, 531 – 534]
Alkylbenzenesulfonate chain distribution: [535]
Fatty alcohol carbon-chain distribution: [536]
Solvents from cleansers: [537, 538]
Propellants in sprays: [539 – 541]
Dioxane in ethylene oxide adducts: [542]
Antimicrobial agents: [513]
Alkoxy content of cellulose ethers: [368]
Nitro musk compounds: [543]
Pentaacetylglucose: [544]
Fragrances by head space analysis: [545]
Supercritical Chromatography:
Nonionic surfactants: [546]
Anionic surfactants: [546]
Liquid Chromatography: [529, 547 – 549]
Poly(ethylene glycol) in nonionic surfactants: [550 – 552]
Unreacted alkylbenzenes and fatty alcohols in their sulfonation or esterification products: [553]
Bleach activators: [554, 555]
Fatty acid amides: [556]
Separation of fluorescent whitening agents: [518, 557 – 559]
Bacteriostatic substances in soaps: [560]
Nonionic surfactants: [529, 561 – 564, 566]
Anionic surfactants: [562, 563, 565, 567 – 569]
Separation of sulfonic acids: [570, 571]
Separation of lower alcohols: [572]
Separation of sulfur-containing surfactants: [573]
Phosphonates, polyphosphates: [574]
Ion Chromatography: [575 – 577]
Phosphates: [578 – 580]
Phosphonates: [578, 581, 582]
Capillary Electrophoresis: [583 – 585]

7.4.5. Structure Determination

UV Spectrometry: [310, p. 74], [586 – 589]
Alkylbenzenesulfonates: [334, Dd 3–60], [590 – 592]
Toluenesulfonate, xylenesulfonate, cumenesulfonate: [310, p. 205], [593, 594]
Structural information of surfactants: [525, 595]
Toluenesulfonamides: [596]
IR Spectrometry: [310, p. 69], [322, 597 – 604]
Petroleum sulfonates: [525]
Degree of branching in alkylbenzenesulfonates: [605, 606]
Surfactant sulfonates: [607, 608]
Soil antiredeposition agents, cellulose derivatives: [609]
NMR Spectrometry: [310, p. 86], [610, 611]
Ethylene oxide–propylene oxide adducts: [310, p. 301], [529, 612, 613]
LAS: [614, 615]
Mass Spectrometry: [310, p. 76], [616 – 619]
Fragrances (GC–MS): [620, 621]
Bactericides (TLC–MS): [310, p. 426], [626]
Nonionic surfactants (LC/FAB–MS): [622, 623]
Nonionic surfactants (MS): [624]
Nonionic surfactants (GC/CI–MS): [625]

7.4.6. Determination of Characteristic Values

Elemental Analysis: [627]
Nitrogen: [310, pp. 124 and 444], [627, p. 178], [628]
Halogen: [310, p. 128], [629, 630]
Sulfur: [310, pp. 126 and 439], [627, pp. 252 and 307], [630]
Phosphorus: [310, p.129], [397, pp. 899 and 902], [627, p. 360]
Fat Analysis Data: [376, 631]
Acid number: [310, p. 182], [333, C–V 2 (77)]
Saponification number: [310, p. 183], [333, C–V 3 (57)]
Iodine number: [310, p. 183], [333, C–V 11 a–d (53)]
Hydrogen iodide number: [333, C–V 12 (53)]
Hydroxyl number: [310, pp. 186 and 303], [333, C–V 17 a + b (53)]

7.4.7. Analysis Automation: [632]

Phosphorus pentoxide: [633 – 635]

Enzymes: [636, 637]

7.5. Sources of Information: [326, p. 403 (1981)]

8. Test Methods for Laundry Detergents

All detergent test methods have the establishment of product quality as their goal. "Quality" is taken to include all those subjectively judgeable and objectively measurable properties of a product that play a significant role in its application.

Many possible approaches are available for measuring detergent quality, but these can be subdivided into three major groups:

Laboratory methods
Practical evaluation
Consumer tests

8.1. Laboratory Methods

Practical evaluations require careful statistical analysis of increasing numbers of test series, most of which are time-consuming and associated with high labor and material costs. For this reason, development of preliminary and screening test procedures has become necessary, as well as suitable laboratory methods for obtaining useful and relevant information, especially for development work. Such tests are designed to approximate service conditions to which the products will actually be subjected. The tests generally produce valuable clues to product quality, but their results should not be overrated, since the circumstances under which they are obtained are not totally identical to those that apply in the field. Normally these tests are conducted with laboratory equipment specially designed for small-scale tests (e.g., Launderometer [641], Linitest equipment [642], Terg-o-tometer [643], and various foam testing equipment [644, 645]).

In place of naturally soiled domestic laundry, use of artificially soiled and stained textiles and test swatches is standard in laboratory tests.

These swatches are prepared by using various standardized fabrics and knitware and various soils and stains. The swatches are often commercially available [646]. In addition, individual stains are prepared in the laboratory for specific purposes, either by hand or using special equipment. Artificially soiled fibers or fabrics must be prepared so that they respond selectively to different detergent components and different sets of washing conditions if adequate differentiation is to be assured. The amount of a certain soil on every swatch is identical and it is evenly distributed.

Criteria for testing detergents are subdivided as follows:

- Single wash cycle performance (soil and stain removal and bleaching)
- Multiple wash cycle performance, e.g., after 25 or 50 washes (soil antiredeposition properties, degree of whiteness, buildup of undesirable deposits, fiber damage, stiffness, color change, fluorescent whitening)
- Special characteristics (powder characteristics such as density, free flowability, dispensing in a washing machine, homogeneity, dusting properties, solubility, foaming, rinse behavior, and such storage characteristics as chemical and physical stability, hygroscopicity, color, odor, and tendency to form lumps)

The literature describes numerous methods for testing according to the above criteria, some of which are standardized. Standardization is a concern not only of national bodies (e.g., ANSI, the American National Standards Institute; JISC, the Japanese Industrial Standards Committee; DIN, Deutsches Institut für Normung [647]; AFNOR, Association Française de Normalisation; BSI, British Standards Institution), but also of international groups (e.g., ISO, International Organization for Standardization).

The above national organizations are all members of ISO and can, therefore, exercise influence on questions of international standardization [648]. Another particularly important organization concerned with international standardization of test methods is the CID (Comité International des Derivés Tensio-Actifs) with its subcommittee, the CIE (Commission Internationale d'Essai). This organization was disbanded in 1978, but in the meantime, its activities have been taken over and carried forward by the Working Group TMS (Test Methods for Surfactants) of the CESIO (Comité Européen d'Agents de Surface et Intermédiaires Organiques).

8.2. Practical Evaluation [649 – 653]

Practical wash evaluation is conducted with the exclusive use of commercial washing machines. In contrast to pure laboratory investigations and screening procedures, this work is carried out with laundry whose soil has been acquired naturally. The purpose of such experiments is to obtain results that can be regarded as far more realistic. Nonetheless, it is impossible to encompass the entire spectrum of conditions that might be encountered in practice. In many cases, so-called anonymous domestic laundry is tested: laundry of household origin, but not otherwise identified. Far better, however, even though more difficult to arrange, are wash-and-wear tests conducted by using specific new fabric items, e.g., terry towels, dish towels, shirts, pillow cases, etc., that have been distributed for regular use during a certain period (usually a week) in a sufficient number of representative households. After each use cycle, the samples are collected in the laboratory and washed with the detergent being evaluated. The same item must always be washed with precisely the same detergent and under identical washing conditions. The number of necessary wash-and-wear cycles depends on the nature of the questions being investigated. Nonetheless, usually ca. 15–25 wash-and-wear cycles are necessary, occasionally even more. The detergent is generally used according to the manufacturer's directions, although effects of under- and overdosing may also be taken into account. Analytical precision is improved if instrumental methods are used to evaluate test results, but such measurements are sometimes difficult both to interpret and to conduct. Thus, an alternative evaluation is based primarily on visual evaluation, with physical measurements used only in a supporting role. Recommendations for comparative testing of detergent use characteristics have been the subject of a tentative DIN standard [654], as well as an ISO standard [655].

In the interest of both manufacturers and especially consumers, comparative use tests must be conducted under the most realistic conditions.

This is particularly true of tests designed for consumer education, such as those carried out by consumer organizations; otherwise the results are of little value. Therefore, good communication and close contacts between the consumer organizations and the product manufacturers regarding test methods and criteria to be applied prior to conducting the tests is of paramount importance. Oversimplified tests, e.g., those using artificially soiled swatches only, are incapable of making the sorts of distinctions that consumers consider relevant, and are a disservice to all parties concerned. Ultimate product judgements must be based not only on wash results, but on all of the relevant factors affecting use value.

8.3. Consumer Tests

To obtain a final degree of certainty with respect to a detergent's use characteristics and acceptance, consumer tests are conducted in addition to laboratory tests as a regular control to determine consumer acceptance. In such tests, consumers subject a product to their own sets of conditions; i.e., they use their own washing machines on their own laundry and soil, and it is assumed that they introduce the detergent in the manner to which they are accustomed. The precision of such in-home use tests is of course limited, because consumers judge, they do not measure. Therefore, it is necessary that a large number of consumers (usually 200–300 households) participate if statistically meaningful conclusions are to be drawn. Experience has shown that such tests are of high value in addition to laboratory results, both for determining product weaknesses and for identifying particular strengths. By their very nature, consumer tests subject a product to a great many different sets of circumstances, and they lead to very meaningful results. Thus, consumer tests are very frequently conducted prior to marketing a new product.

9. Economic Aspects

The worldwide economic role of detergents represents a factor of considerable importance. Nonetheless, laundry detergent consumption per capita varies tremendously from country to country (Fig. 91 [216]). Changing patterns of use for laundry detergents and increased standards of living over the last 40 years reveal a remarkable growth in worldwide consumption, with the absolute quantity rising from approximately 10×10^6 t in the late 1950s to 21.5×10^6 t worldwide in 1998.

Total consumption of laundry, dishwashing, and cleaning detergents in Europe was 6.4×10^6 t in 1991. Eight years later it was 6.8×10^6 t, corresponding to a volume growth rate of nearly 1 % per year (Table 42 [656]).

Table 42. World total surfactant consumption by end use, 1992 and 1998 (10^3 t) [657]

End use	1992	1998
Household		
North America	866	1115
Western Europe	1061	1119
Asia	1208	1599
Other regions	998	1235

Asia	858	1085
Other regions	355	364
Total *	**3048**	**3441**
Grand total	**8253**	**9862**

* Does not include soap.

Only a handful of large companies manufacture most of the world's laundry detergents and cleansing agents. The leaders are Procter & Gamble (Cincinnati, Ohio, USA) and Unilever (London, UK and Vlaardingen, The Netherlands). Further internationally operating major manufacturers are Colgate Palmolive (New York, USA), Henkel (Düsseldorf, Germany), Reckitt Benckiser (Windsor, UK), Kao (Tokyo, Japan), and Lion (Tokyo, Japan). In the U.S. market, four firms (Procter & Gamble, Lever, Dial, and Colgate) dominate. The remainder

is split among many smaller local or regional producers. In Europe, for example, the Association Internationale de la Savonnerie, de la Détergence et des Produits d'Entretien (AISE), a trade association made up of European national detergent industry groups, estimates that its members represent some 1200 individual firms.

9.1. Detergent Components

Production capacity and demand for the major detergent raw materials by volume are briefly reviewed in the following sections.

9.1.1. Surfactants [657]

World surfactant consumption was estimated at 9.9×10^6 t in 1998, corresponding to an increase of 20 % since 1992 (Table 42). The two largest end uses, household products and industrial processing aids, together account for for 86 % of the total. Household products alone accounted for nearly 5.1×10^6 t, or half of the world total. Household products include heavy-duty powder and liquid detergents, light-duty liquids, and fabric softeners. The regional distribution of surfactants consumption for houshold use in 1998 is shown in Figure 119.

Figure 119. Surfactant demand for household use in 1998 [657]

Industrial processing aids cover five major end uses: plastics and elastomers, textiles, agricultural chemicals, leather and paper chemicals, and other miscellaneous uses. The other major categories featured include personal care products and industrial and institutional (I& I) cleaners, which together consumed about 1.4×10^6 t of surfactants in 1998. I& I products include laundry products, hard-surface cleaners, and dishwashing detergents. From data shown in Figure 120 it is obvious that the two major sectors of the total world surfactant market are the household and I& I areas. Surfactant consumption grew most rapidly in Asia in the 1990s (> 30 %), whereas Europe showed only a moderate growth (< 10 %) in that period.

Breakdown of total surfactant consumption by type is depicted in Table 43. Apart from soap, which is the world's largest surfactant by volume (worldwide consumption 8.8×10^6 t in 1999 [658]), surfactant consumption is headed by anionic surfactants, viz. linear alkylbenzenesulfonates, alcohol sulfates, and alcohol ethoxy sulfates. Second in consumption are alcohol ethoxylates and alkylphenol ethoxylates. LAS has remained the most widely used synthetic surfactants. They have weathered the environmental concerns and experienced a comeback in Europe. They continue to dominate in the Americas and Asia.

Table 43. World major surfactant consumption by type, 1992 and 1998 (10^3 t) [657]

Surfactant type	1992	1998
Linear alkylbenzenesulfonates	2385	3027
Branched alkylbenzenesulfonates	411	198
Alcohol sulfates	466	479
Alcohol ethoxysulfates	511	911

9.1.2. Builders

Sodium triphosphate has been the most important detergent builder in powder detergents since

Figure 120. Total surfactant end user markets in 1998 [657]

the 1950s worldwide. Its use has become a subject of intense public discussion in many countries in the last 30 years as a result of phosphate-induced regional overfertilization of surface waters. In countries where overfertilization has been particularly severe, this has resulted in both voluntary agreements and legal restrictions, which have caused a sharp decrease in the use of sodium triphosphate for washing and cleansing purposes, mainly in the USA, Europe, and Japan. Within ten years, the use of sodium triphosphate in detergents dropped by more than 50 % in these regions [659, 660]. Worldwide production capacity has risen dramatically for the most important phosphate substitute zeolite A. Figure 121 shows the increase in production capacities for zeolite A in Western Europe in the 1980s and 1990s [169]. Additional major manufacturing capacities are located in the USA, Japan, and Taiwan. Meanwhile, production capacities for detergent-grade zeolites have largely surpassed demand.

Quantitatively, detergent builder zeolites represent the largest application field for zeolites [660]. Almost 90 % or 1 050 000 t/a of zeolites produced worldwide in 1994 were used for detergents. Of this, ca. 950 000 t/a were zeolite A and some 100 000 t/a were of the zeolite P type.

Figure 121. Production capacities of zeolite A in Europe (10^3 t) [169]

In Japan, for example, since the mid-1980s more than 95 % of all detergents produced and sold are phosphate-free, containing zeolite instead. Also in the USA meanwhile nearly all laundry detergents are nonphosphate products. A large portion of them contains zeolite A as the main builder. The situation in Europe is illustrated in Figure 99 [218]. Here, too, zeolite is the main builder for phosphate-free laundry products. The replacement of phosphate by zeolite A has gained additional momentum as a result of changes in the prices for raw materials.

The economic situation with respect to other detergent ingredients is highly variable from continent to continent. Moreover, these mate-

rials are used in smaller quantities. Hence, their economic impact is less significant and will not be dealt with here.

9.2. Laundry Detergents

In 1998, total world production of soap bars and laundry detergents was 21.5×10^6 t. Again, the tonnage varies among the global regions and individual countries (Table 44).

Worldwide, powder detergents continue to constitute the largest section of the total textile washing and cleaning products market, both in volume and value terms. The powder detergents category is prominent due to the well-established nature of the standard powder delivery form, and latterly the market performance of the tablet laundry detergents, introduced into several markets in the late 1990s and 2000. Exceptions are the USA, where liquid laundry products took over the lead in the 1990s; Indonesia, whose market is dominated by detergent pastes; and the Philippines, where the vast majority of the consumers use soap bars. India is the world's largest single market by volume for soap bars, but here, too, powders dominate and continue to grow at the expense of bars.

In terms of value, total textile washing products amounted to sales of $ 17.7×10^9 in the seven major single markets (USA, Japan, Germany, UK, France, Italy, and Spain) in 1999 [219]. These markets are best characterized by having a high degree of maturity, along with fierce price competition and high advertising expenditures. Four of these markets registered positive gross value growth over the period 1995 through 1999. This translates into a positive real value growth of the U.S. market of almost 13 %, whereas Germany, Italy, and Japan recorded real value declines of 6.5 %, 11.7 %, and 7.6 %, respectively. Due to their high levels of saturation and maturity, continuous product innovations play an important role in stimulating these major markets.

Within the powder detergents sector, conventional products claim most of the sales in France, Italy, Spain, and the UK, whilst the (super)concentrated powders are more popular in Germany, Japan, and the USA for various reasons, such as space-constraints in the home (Japan), reduced packaging costs, space-saving benefits, and consumers' greater environmental awareness (Germany), as well as consumer perceived greater convenience and product benefits vs. retail price (USA).

In the liquid detergent sector, concentrated products form the larger subsector in Germany, Japan, the UK, and the USA. Conventional liquid detergents lead in France, Italy, and Spain.

Within the category of other detergents, fine-fabric specialty detergents lead in most of the seven major markets, ahead of hand-washing detergents and detergent bars. Changing lifestyles and increased saturation of the washing-machine market have contributed to considerably reduced consumption of products of the last two subsectors.

9.3. Fabric Softeners

Europe is the major consumer of rinse-cycle fabric softeners. A number of reasons explain this, including the fact that European tap water on average is relatively hard and the fact that the vast majority of drum-type washing machines are equipped with separate dispensers for laundry aids in Europe. Apart from the USA and Japan, products in this class continue to be relatively insignificant in volume in the restof the world. Figure 122 provides information about European fabric softener consumption for the year 1999. These consumption figures represent both conventional fabric softeners, which contain 4 to 8 % active ingredients, and concentrated softeners, which usually have 12 to 30 % active cationics. After a period of decreasing consumption in the 1980s, fabric softeners enjoyed growth in both value and volume in the 1990s.

Concentrated fabric softeners have dramatically increased their market share at the expense of diluted conventional softeners. The shares of concentrated softeners in Europe in 1998 varied from some 20 % in Italy to 98 % in Germany. Use of concentrated products saves packaging materials and transportation costs and reduces the amount of waste. To further decrease waste, part of the concentrated fabric softeners are sold as refill packages in many European countries. Their share of total concentrates varies from 10 % in Belgium to some 65 % in France. Fabric softener sheets, which are very popular in the USA as laundry dryer aids, find only very limited

use in Europe and Japan. The share of softener sheets ranges from 0 to 5 % of the fabric softener market in European countries.

Total consumption of fabric softeners in Japan was some 250 000 t in 1998, about 40 % of which were concentrated products.

9.4. Other Laundry Aids

In the seven major detergent markets, laundry aids comprise a wide number of subcategories, with spot and stain removers and laundry bleach claiming the leading positions in most key markets. Although chlorine bleaches have been used for textile washing for many years, the introduction of color-safe, non-chlorine bleaches led to a considerable consumption of this subcategory in the 1990s. Laundry bleach accounts for the largest share of sales in the USA, Spain, and Italy.

10. Ecology

10.1. Laundry, Wastewater, and the Environment

The washing process represents a complex interaction between soiled laundry, water, mechanical and thermal energy, and detergents. Laundry is repeatedly cycled through the system, and clean laundry can be regarded as the product. Wastewater is the troublesome byproduct which has the potential for causing a number of undesirable effects in sewage treatment plants and in the environment. Virtually all of the clean water brought into the process is later released to the sewage system in the form of contaminated wastewater containing additional energy (heat), soil from the laundry, lint, dyes, finishing agents, and detergents. Detergent components are released to the wastewater either in essentially unchanged form or as the products of reaction with other materials present.

Laundry wastewaters vary considerably in concentration and composition. These differences arise partly due to variations in laundry soil levels, although washing technology and the composition and amount of added detergent are also significant factors. The differences are particularly great between the wastewaters generated by household laundry and those from I& I laundries. The latter generally contain lower portions of contaminants originating from detergents, largely as a result of more economical use of typical I& I laundry products and the use of water-softening equipment. Little doubt exists that laundry wastewater must be generally regarded as a heavily contaminated medium; it should not be returned to receiving waters in untreated form.

Fortunately, the wastewater emanating from the hundreds of millions of household washing machines and from washing by hand worldwide is widely distributed, and in a pattern consistent with that of general water consumption. As a result of dilution in the public sewerage system and in sewage treatment plants, both the temperature and the relatively high pH value of wastewater are considerably decreased, and the effect of peak loads is also somewhat compensated for. Only for this reason is biological treatment of laundry wastewater in a normal sewage treatment plant feasible. If laundry wastewater were treated separately, major problems would be encountered in dealing with the load of organic pollutants introduced by household and commercial laundry operations. Dilution of laundry wastewater within a typical public sewage system normally exceeds a factor of ten.

10.2. Contribution of Laundry to the Sewage Load

Table 45 presents calculated estimates of average theoretical concentrations of the detergent and cleanser components in public wastewater. These estimates are derived from statistical data collected in Germany and depend on both product consumption and the average water consumption in households. These calculated average wastewater concentrations are "worst-case" assumptions, since the average per capita wastewater production rate (combined household and commercial) is around 200 L/d in the EU member states.

In addition, the calculated concentrations of some of the chemicals are only partly due to the use in laundry detergents since other applications (e.g., dish washing and cleansing products) may contribute to a considerable extent. Furthermore, actual values for concentrations and loads show considerable variation. Time of day is a factor, as is the day of week (with Saturdays and Mondays producing the highest values). Even seasonal variations are apparent, but all of these fluctuations are reasonable when examined in the light of known household laundry habits [662].

A significant portion of domestic water is used in the household laundering operation. According to [663], the per capita amount of laundry wastewater generated daily is around 17 L, which translates into 13 % of the domestic water consumption or about 8 % of the total hydraulic load reaching a sewage treatment plant. Not only in terms of the hydraulic load but also with respect to the chemical load, the laundry washing process is a major factor influencing municipal wastewater. As shown in Table 46, the detergents contribute about 10 % to the COD, the biodegradable organic matter (usually reported as the BOD_5), and the dry solid matter content of the municipal wastewater load, while the contribution to the nitrogen and phosphorus load is low. In addition, of course, the soil contained in soiled laundry represents another important contributor to the load of wastewaters. About half of the biodegradable contaminants load of mixed wastewater derived from laundering is due to laundry soil and stains. The amount of organic contamination originating from soil is doubled or tripled in institutional laundry wastewaters, compared to laundry wastewater from households.

10.3. Detergent Laws

Detergents represent a typical and important group of environmental chemicals, i.e., substances entering the environment after their use. The per capita consumption of detergents is nowadays at a level considerably below the figures of the 1980s (1980: 33.3 g per capita and day in Western Germany; 1997: 21.1 g per capita and day in Germany). Nevertheless, the 1999 consumption was in the range of 660 000 t/a (Table 45). These large amounts of chemicals go down the drain and enter receiving waters directly or after sewage treatment. Since the wastewater treatment situation was relatively poor in most European countries a few decades ago, it is not surprising that certain detergent ingredients, i.e., surfactants and phosphates, exhibited an apparent specific impact on the aquatic environment and became subject of specific laws and regulations.

10.3.1. Development of the European Detergent Legislation

One of the earliest pieces of detergent legislation was the German Detergent Law of 1961

Table 45. Consumption figures and average wastewater concentrations of ingredients of household detergents and cleansers (Germany, 1999)

Product ingredient	Consumption, t/a [661]	Per capita consumption, g/d[a]	Calculated average wastewater concentration, mg/L[b]

[44]. With its specific requirement for a minimum level of biodegradability, this law subjected a fundamental product parameter to legal control for the first time. The trigger for setting minimum biodegradability standards for synthetic detergents was the fact that the first generation of synthetic anionic surfactants was represented by the poorly biodegradable tetrapropylenebenzenesulfonate. The highly branched chemical structure of the anionic surfactant prevented its microbial degradation in sewage plants and rivers and caused formation of large mountains of foam in sewage treatment plants, weirs, locks and rivers in Germany, particularly during the droughtlike summers of 1959 and 1960. The law and the statute that followed (1962) [45] placed a strict requirement of at least 80 % biodegradability on all anionic surfactants. This legal move successfully displaced TPS from detergent formulations by the readily biodegradable linear alkylbenzenesulfonates. Thus, by 1965 foaming problems in German sewage treatment plants and surface waters had been eliminated.

In the late 1960s most of the European countries had limited the use of TPS in household

detergents. Based on an agreement of the Council of Europe [665] requiring all types of surfactants to be biodegradable, the EEC released two directives on the biodegradability of surfactants in 1973: The EEC Directive 73/404/EEC stipulated an average biodegradability of at least 90 % for all types of surfactants used in detergents, i.e., anionic, nonionic, cationic and amphoteric surfactants [666]. The Directive 73/405/EEC described the biodegradability test methods to be applied for anionic surfactants and specified a minimum of 80 % degradation in a single test [667].

On the national level these European Directives were translated into detergent laws by the member states, e.g., in Italy in 1974, France in 1977, The Netherlands in 1977, and the UK in 1978 [668]. In Germany the detergent law of 1975 [669] and its statutory orders of 1977 [670] and 1980 [671] regulated the "environmental compatibility of laundry detergents and cleansers". According to § 1 (1) of the German Detergent Law placement of detergents and cleansers on the market is permitted only if the absence of all avoidable deterioration in the quality of surface water can be ensured. Particular attention is paid to the potential role of surface water in the drinking water supply and to problems related to the operation of sewage treatment plants. The general requirements and authorizations for implementation apply directly to the following areas:

1) Unambiguous product labeling, including qualitative declaration of all significant components present
2) Deposition of frame formulations for all products at the Federal German Environmental Agency
3) Utilization only of biodegradable organic components, particularly surfactants and other organic compounds as specified in a statutory order
4) Provision of directions for dosage of detergents on all packages, including variations applicable to water of differing hardness, where hardness is defined in terms of four ranges
5) Obligation on the part of local water supply authorities to publish the hardness characteristics of their water
6) Limitations on permitted phosphate levels, including some cases of a total phosphate ban, provided that ecologically sound substitutes are available (see Section 10.3.4)

Products covered by the Detergent Law include: household laundry detergents; household cleansers; dishwashing agents; rinsing and other laundry aids; detergents for I& I laundries; industrial cleansers; and cleansing agents employed in the leather, tanning, paper, and textile finishing industries that might be released into wastewater.

Thus, the definition of detergent products according to the German Detergent Law is more comprehensive than the EU definition, that only covers surface active substances which are main components in detergents and designed for cleaning purposes [668].

10.3.2. Regulatory Limitations on Anionic and Nonionic Surfactants

The Directive 73/405/EEC [667] and its updated version Directive 82/243/EEC [672] specify the minimum biodegradability of anionic surfactants contained in detergents. In addition, the procedures are described to be applied for measurement of biodegradability. In close analogy the Directive 82/242/EEC [673] specifies an 80 % biodegradation pass limit for nonionic surfactants used in detergents, and the test methods to be used. A corresponding national regulation has existed in the Federal Republic of Germany already since 1977 [670] ("Tensidverordnung"). The regulation requires a minimum of 80 % biodegradability for the anionic and nonionic surfactants present in a packaged detergent. Anionic surfactants are determined as "methylene blue active substances" (MBAS), i.e., materials forming a chloroform soluble complex with the cationic dye methylene blue. Nonionic surfactants are defined as "bismuth active substances" (BiAS), i.e., materials forming an insoluble complex with the bismuth-containing Dragendorff reagent [674].

Although not all anionic and nonionic surfactants can be analytically measured by the MBAS and BiAS method [675], these parameters are used for the evaluation of the biodegradability according to the legal requirements. Essentially, the percentage of MBAS or BiAS loss describes

the disappearance of a specific analytical reaction of the parent surfactant. This loss of reactivity is due to microbial transformation of the chemical structure of the surfactant, resulting in the loss of typical surfactant properties such as surface activity and foaming power. Therefore, it is called "primary or functional biodegradation" (see Section 10.4.2.1).

10.3.3. Primary Biodegradation Test Procedures

According to the Directives 82/243/EEC and 82/242/EEC and corresponding national legislations two types of test methods are applicable for determining the (primary) biodegradability of anionic and nonionic surfactants, respectively. The first type is a discontinuous shake flask test operating with a low bacterial inoculum, that is incubated with 5 mg/L of MBAS or BiAS as the sole carbon source. In this *OECD Screening Test* [676] the loss of MBAS or BiAS is determined periodically up to 19 d. The results are compared with the degradation behavior of two control substances: the poorly degradable TPS (< 35 % MBAS decrease) and the readily biodegradable LAS (about 92 % decrease). The biodegradability determination in this test is illustrated in Figure 123. The second test type is represented by the *OECD Confirmatory Test* [676] simulating the biodegradation process occurring in an continuous activated sludge plant (Fig. 124). In this procedure, MBAS (20 mg /L) or BiAS (10 mg /L) is dissolved in synthetic sewage (containing peptone, meat extract, urea, and mineral salts) and fed continuously into a model sewage treatment plant with a hydraulic retention time of 3 h. After inoculation of the test system with the effluent of a predominantly domestic sewage treatment plant and after growth of the activated sludge, the effluent is analyzed periodically. This running-in period lasts six weeks at maximum and is followed by a 21-d evaluation period after the degradation rate has become regular. The average degree of biodegradation during the evaluation phase is calculated as a mean value of at least 14 separate results based on samples from 24-h collection periods (Fig. 125).

Figure 123. Biodegradability evaluation in the OECD Screening Test
t_A: maximum 14 d; $t_A + t_X$: maximum 19 d
— examples for two surfactants; one is biodegrated more easily (t_A) than the second one ($t_A + t_X$)

Figure 124. Experimental arrangement for the OECD Confirmatory Test as specified by the German Detergent Law
a) Sample container; b) Dosage pump; c) Activated sludge vessel (capacity 3 L); d) Settling vessel; e) Air lift; f) Collection vessel; g) Fritted disk; h) Air flow meter

The discussed test types represent a hierarchical system of the biodegradability evaluation. Usually, surfactants are evaluated on the basis of die-away screening tests such as the OECD Screening Test or the French AFNOR Test. In addition, the British Porous Pot Test, which is a continuous sewage works simulation test, may be used at this stage of data generation [672, 673]. However, if the degradation proves MBAS or BiAS loss lower than 80 %, or if doubt remains, a subsequent confirmatory test is required, and the outcome of this OECD Confirmatory Test is regarded as definitive.

Figure 125. Determination of a rate of biodegradation according to the method specified in the OECD Confirmatory Test

10.3.4. Regulation of Maximum Phosphate Content in Detergents

The detergent regulations at the European Union level address exclusively the surfactants and their biodegradability. However, at national levels, regulations or voluntary agreements on the phosphate content of detergents exist in many countries, e.g., Austria, Germany, Italy, The Netherlands, Norway, Sweden, Switzerland, USA, Canada, and Japan.

In itself, phosphate is not harmful but is a natural and essential macronutrient for all living organisms. Normally, the phosphate concentration of surface waters is so low that it is a limiting factor for growth of algae and higher plants. Consequently, when excess phosphate is released into the aquatic environment, the resulting overfertilization leads to increased growth of algae. Due to the concomitant secondary processes (organic load of waters, oxygen depletion after the organic bio-mass is microbially degraded) the overall water quality may be considerably reduced. Detergent phosphates released with laundry wastewater are quickly converted into orthophosphate. Thus, the use of sodium triphosphate in detergents came under critical scrutiny although many other phosphate sources exist that contribute to eutrophication of surface waters.

According to a profound study on phosphates in Germany in 1975, some 60 % of the phosphate contained in municipal sewage originated from detergents and cleansers [677]. As a consequence of the partial removal of phosphate in sewage treatment plants and the input of phosphates by other sources (human excretion, food industry, agricultural fertilizers), the share of detergent phosphates in surface waters was estimated to be about 40 %. This balance showed already that the reduction of phosphates in detergents is an important but not the sole factor in solving the eutrophication problem of surface waters.

The most comprehensive approach involves chemical elimination of phosphates in the sewage treatment plant (tertiary treatment) removing the total phosphorus content of the wastewater. This approach is realized in some countries to a greater or lesser extent. Nevertheless, phosphate reduction in detergents, i.e., at its source, provides immediate relief to receiving waters and, ultimately, also to the coastal areas of the seas, which are increasingly confronted with eutrophication problems. The phosphate regulation of 1980 [671] implementing the pertinent authorization of the German Detergent Law of 1975 (see Section 10.3.1) had a considerable impact on the development of the phosphate loads in German rivers (Fig. 126). The phosphate reduction in detergents was enforced in a two-step decree starting with an overall relative decrease of 25 % of the detergents' phosphate in 1981 and around 50 % in late 1983. The second step required the availability of suitable phosphate substitutes for detergents (see Section 10.5.2). Their good performance in phosphate-reduced and -free detergents and the acceptance of nonphosphate detergents by the consumer has meanwhile led to a complete substitution of phosphate-containing detergents by phosphate-free ones in many countries, for example in Eu-

Figure 126. Variations of the orthophosphate load in the river Rhine from 1981 to 1999 (sampling site: Düsseldorf-Himmelgeist, Germany)

rope in Germany, the Scandinavian countries, Italy, Austria, The Netherlands, and Switzerland (see Fig. 99). Thus, the legal requirements on reduction or banning phosphates in detergents have been superseded in many cases by the industrial supply of efficient phosphate-free detergents and their acceptance by the consumer.

The legislative pressure towards phosphate reduction in detergents accompanied by the availability of suitable substitutes has resulted in a noticeable quality improvement of a number of surface waters today [678]. Phosphate balances of the river Rhine in 1979 and 1989 showed that the measured phosphorus load reduction of about 28 400 t/a within this period corresponded very well with the expected phosphorus reduction due to the use of phosphate-reduced or -free detergents (26 700 t/a) [679].

10.4. General Criteria for the Ecological Evaluation of Detergent Chemicals

The history and the development of the detergent legislation in Europe impressingly reflects the environmental relevance of this group of anthropogenic chemicals (xenobiotics) encountered already in times when the terms "environmental safety" or "environmental risk assessment" were not yet used. The lesson of the so-called detergent problem of the late 1950s was learned both by the legislators and the detergent industry long before general criteria were developed and applied for the ecological evaluation of chemicals. Now, such broadly applicable instruments and standards have been available for several years, e.g., the risk assessment directives for new and existing chemicals of the European Union [680, 681] and the accompanying Technical Guidance Documents [682] that provide an evaluation system applicable by authorities and industry as well. This chapter deals with the concept and the methods of the environmental compatibility assessment that form the basis for the evaluation of chemicals in general.

10.4.1. Concept (see also → Ecology and Ecotoxicology, Chap. 3)

Production, use, and disposal of chemical products has a more or less significant impact on the environmental compartments water, soil, and air. To secure that such emissions will not negatively influence the biota of these compartments it is necessary that a possible ecological risk is already recognized before the product enters the environment. The environmental safety of chemical products is essentially based on the safety of their individual ingredients. Thus, the product safety assessment must concentrate on the identification of possible risks of the raw materials. Two main issues exist that are relevant to safety or risk assessment:

1) The environmental fate of detergent ingredients and the resulting concentrations in the affected environmental compartments. The final outcome of such an exposure assessment is the predicted environmental concentration (PEC).

2) The environmental effects of a chemical towards the living organisms of the compartments concerned. The final result of such an effects assessment is the predicted no-effect concentration (PNEC).

Table 47. Elements of environmental safety assessment of chemicals

	Environmental fate	Environmental effects
Substance-inherent properties (hazard identification)	biodegradability	ecotoxicity
Environmental frame conditions (healistic worst case)	exposure scenario, e.g., – usage quantities – use pattern – sewage treatment situation	extrapolation of effect data: laboratory data → real environment (extrapolation factors)
Evaluation (hisk hharacterization)	exposure analysis: predicted environmental concentration (PEC)	effects assessment: predicted no effect concentration (PNEC)
comparison: PEC vs. PNEC (No risk: PEC < PNEC)		

The comparison of these two assessment parameters, PEC versus PNEC, forms the basis of the internationally used concept for the environmental risk assessment of chemicals: a chemical is considered safe if the PEC is not higher than the PNEC. The environmental fate and effects of a chemical and the risk assessment based thereon are governed essentially by the inherent properties of the individual chemical such as biodegradation behavior and ecotoxicological properties. The connection of these intrinsic substance properties with the concrete conditions of use of the substance — e.g., the use pattern and the usage figures of the chemical, the sewage treatment situation, the application of safety factors, etc. — provides the data necessary for the calculation/measurement of PEC and PNEC (Table 47).

10.4.2. Environmental Exposure Assessment

The chemical compounds contained in detergents are typical representatives of xenobiotics intended to go down the drain after their use and thus to enter receiving river waters directly or after passing a sewage treatment plant. Depending on their physicochemical properties (for example solubility, adsorption behavior, volatility), these substances can be distributed in environmental compartments such as the water phase, sediment, sludges, soil, etc. The knowledge of the fate and the resulting environmental concentrations are therefore a prerequisite and a decisive criterion for risk evaluation.

10.4.2.1. Biodegradation

Biodegradation is the most important mechanism for the ultimate removal of organic com-

Figure 127. Terms of biodegradability evaluation exemplified by the degradation pathway of fatty alcohol sulfate

pounds from sewages, surface waters and soils. It is a stepwise process mainly effected by aerobic microorganisms, i.e., in the presence of oxygen (Fig. 127). In a first step the parent compound is transformed to a first degradation product (primary degradation), which is subsequently degraded to a second, third, etc., intermediate, i.e., to metabolites with decreasing molecular mass and structural complexity. Ultimately, the total organic structure of the starting material has been decomposed to mineralization products (carbon dioxide, water, inorganic salts) and, in parallel, partly transformed into bacterial biomass (ultimate biodegradation).

The term "primary degradation" only refers to the first steps of the degradation process. Nevertheless, the proof of a fast and quantitative removal of the parent compound is of high ecological relevance for certain chemical classes, e.g., for surfactants. As a rule, the primary degradation of surfactants significantly reduces their surface activity (including their foaming properties) and their aquatic toxicity. For that reason, the European detergent legislation requires a minimum primary biodegradability for anionic and nonionic surfactants (see Section 10.3). Nevertheless, ultimate biodegradability is the decisive criterion for the long-term fate of a chemical and its degradation intermediates in the environment, because this will guarantee the complete re-integration of all components of the substance into the natural material cycles.

10.4.2.2. Biodegradability Standard Test Methods

Primary and ultimate biodegradability of organic chemicals can be evaluated by using suitable test methods (Table 48).

The determination of the removal of the parent compound (primary degradation) requires the availability of a substance- or a substance-group-specific analytical determination method. As discussed previously (see Section 10.3), the primary biodegradation of anionic and nonionic surfactants is determined in standardized tests by measuring the removal of MBAS and BiAS, respectively. The ultimate biodegradation of chemicals can be followed in the tests by means of nonspecific analytical parameters such as carbon dioxide evolution, the BOD, or the removal of dissolved organic carbon (DOC).

Primary and ultimate biodegradability of test substances is normally evaluated by applying standardized and internationally used (OECD, ISO, EU) test procedures (Table 48). The most broadly used category of tests are the screening tests representing simple but stringent evaluation procedures. For instance, the OECD Screening Test determines the primary biodegradation of anionic and nonionic surfactants. The corresponding ultimate biodegradability screening tests are represented by the OECD tests for ready biodegradability (OECD 301 A–F) [683], e.g., the DOC die-away test (OECD 301 A), the CO_2 evolution test (OECD 301 B), or the Closed Bottle Test (OECD 301 D). If the pass level of 60 % BOD (compared to the COD) and CO_2 evolution, respectively or of 70 % COD is surpassed within the four-week test duration, it can be concluded that ultimate biodegradation of the chemical will proceed readily in the real environment [683].

It is a common feature of screening tests that a few milligrams of the test substance are diluted or suspended in a test vessel containing an aqueous mineral medium. This mixture is inoculated by adding a small amount of a bacterial suspension, in most cases originating from a municipal sewage treatment plant (30 mg/L of activated sludge or $\leq$ 10 ml/L of plant effluent). Thus, the test inoculum contains the microorganisms ubiquitously present in wastewater treatment plants and receiving river waters. The degradation process can be analytically followed by substance-specific methods as well as by summary parameters since the test substance is the only carbon source for the degrading organisms in such a screening test system.

Due to the stringency of the screening tests, a negative or poor degradation result obtained in such a system is not necessarily a proof of lack of biodegradability in the real environment. To obtain a realistic view of the biodegradation behavior under practical conditions, model test systems are used simulating the primary and ultimate biodegradation process in the biological stage of a municipal sewage treatment plant (Table 48). In contrast to screening tests, the test chemical is continuously dosed to the model plant resulting in a hydraulic retention time of 3–6 h. Another important difference to screening

Table 48. Standard test of biodegradability assessment

	Screening tests	STP-simulation tests *
Characteristics	simple discontinous flask tests test chemical is sole carbon source low bacterial inoculum stringent test conditions, no simulation test	realistic model of a municipal sewage treatment plant continuous test system/limited retention time high sludge concentration
		Examples	primary biodegradation: OECD Screening Test ultimate biodegradation: OECD tests for "ready biodegradability" (OECD 301 series)	primary biodegradation: OECD Confirmatory Test ultimate biodegradation: Coupled Units Test

* STP = sodium triphosphate

tests is the fact that the test material is dosed together with a large surplus of highly biodegradable substances ("synthetic wastewater") to give a competitive situation which also prevails in real domestic sewage treatment plants. The bacterial concentration in a continuous activated sludge model sewage treatment plant is relatively high (ca. 3 g/L of suspended solids). Depending on the analytical test method either the primary degradation in the simulation test (requiring substance-specific analytical methods) can be determined or the substance removal based on summary analytical parameters (DOC, COD). If a nonspecific analytical method is applied, a modified test design is necessary to obtain removal data that specifically refer to the test substance. In the *Coupled Units Test* (OECD 301 A), for example, two model plants are run in parallel [683]. One is the control, which is only fed with synthetic sewage, while the influent of the second additionally contains the test substance. The test substance-related carbon removal can be calculated from the difference of the DOC concentrations in the two plant effluents compared with the carbon content of the substance in the influent of the test unit. Monitoring data on the removal of surfactants in municipal sewage treatment plants have broadly confirmed that the elimination rates obtained in model plants are a realistic or rather a conservative description of the practical situation [684].

10.4.2.3. Supplementary Biodegradation Test Methods

Apart from these internationally used standard degradation tests additional test methods exist to extend the information about the fate of chemical substances in the environment. The results from the previously discussed screening and simulation tests are, in principle, a measure of the degradation rate, i.e., the extent of degradation within the test period. Therefore, the question remains unanswered whether the test-substance-derived material which was not biodegraded within the test period may contain recalcitrant degradation intermediates. In other words, if it is possible to show that no poorly biodegradable intermediates are formed during the degradation process, unknown negative effects from the long-term existence of those materials in the environment can also be excluded. The test for *detecting recalcitrant metabolites* (metabolite test [685]) which is experimentally based on the Coupled Units Test, represents an

instrument for answering this question. Thus, the test for recalcitrant metabolites can improve and supplement the conclusions drawn from positive results obtained in standard degradation tests.

In contrast to the Coupled Units Test, the effluents of the test and the control plants are reused each day as an influent after addition of a concentrate of the nutrients (control unit) and the test substance. Thus, a circuit is achieved which gives the degrading organisms the permanent chance to cope with the test compound and its intermediates under competitive conditions. Since the metabolite test is run over several weeks — corresponding to up to 100 cycles — even very small amounts of recalcitrant metabolites would accumulate and could be analytically detected. The proof of the absence of any recalcitrant metabolites was obtained for all important detergent surfactants by means of this method [686].

The issue of the completeness of the ultimate degradation in the environment has yet another dimension. Substances with a marked adsorption tendency such as surfactants or poorly water-soluble compounds may to a considerable extent reach environmental areas where no oxygen is present for the biodegradation processes of microorganisms. Examples are septic tanks, digesters, some river sediments, and soils. The *anaerobic biodegradability evaluation* is therefore an additional important aspect for those substances. A screening test method has been available for several years (ECETOC Test, ISO 11734 [687]) that measures the ultimate anaerobic biodegradation of a substance on the basis of the digester gas formation (carbon dioxide and methane). In addition, digester simulation tests with radiolabeled test materials have shown the anaerobic biodegradability of important surfactant groups [686].

10.4.2.4. Exposure Analysis

After identification of the environmental areas mainly exposed to the chemical(s) concerned (e.g., wastewater treatment plants, sludges, river waters and sediments, as well as soils are target areas of detergent chemicals) a preliminary exposure analysis may be conducted. The first tier of such a process is based on relatively simple but conservative standard exposure scenarios. Thus, the concentrations of detergent ingredients in raw wastewaters are calculated on the basis of the per capita usage of the product and the ingredient, respectively, and the per capita water consumption (see Table 45). The elimination of the chemical in sewage treatment plants is estimated by means of calculation models taking the physicochemical (adsorption behavior, volatility) and the biodegradability properties (deduced from degradation screening tests) of the substance into account. From the PEC of the chemical in the plant effluent it is possible to derive a PEC of the receiving water by applying a standard dilution factor of 10 for treated wastewater [682].

A more detailed and reliable environmental concentration prognosis can be obtained in the second tier of the exposure analysis when concrete data of the individual environmental situation are taken into account. These data are, for example, elimination data from sewage treatment plant simulation tests and information on the wastewater treatment (e.g., sewage volumes, hydraulic retention time, etc.) and river water situation (e.g., wastewater dilution ratio, flow rate, etc.). In addition, also the background concentration of the substance concerned must be considered, i.e., the PEC above the sewage outfall. This prognosis of the regional distribution is obtained by means of multimedia calculation models, for instance according to MacKay [688], which predict an average PEC in the environmental compartments of water, soil, and air.

The exposure analysis is — as is the whole environmental safety assessment — an iterative process. This means that the precision and reliability of the PEC values can be improved continuously by the improvement of the data and information based thereon. Therefore, it is understandable that the highest tier of the exposure analysis is represented by the measurement of real environmental concentrations, i.e., by environmental-monitoring data. If sufficiently specific and sensitive analytical methods are available and if the chemical concerned is already in use, such measurements can be conducted. Thus, environmental-monitoring data and PEC data from exposure models form a necessary mutual supplement to fill the environmental concentration data gap for most of the chemicals present in the environment. Due to the conservative character of the model cal-

culations there is consensus that the data obtained from real environmental measurements take precedence over calculated values [682].

Detergent ingredients, particularly the most broadly used surfactants (LAS, alcohol ethoxylates, alcohol ether sulfates, soap) have been thoroughly investigated by means of the multitiered approach of exposure analysis. It could be shown that the measured concentrations in raw and treated wastewaters are considerably lower than predicted by the calculation algorithm described for the tier 1 screening phase (cf. Table 49) [689, 690]. Consequently, also the predicted river water concentrations (PEC_{river}) are higher than the measured concentrations reported for several detergent surfactants [684, 691]. The conservatism of the model calculations is also connected with the fact that the biodegradation/elimination processes of chemical compounds are only considered with regard to the removal in sewage treatment plants, while an in-stream removal after entering the receiving river is not taken into account or is based on over-conservative assumptions [692]: for instance, the half-life for LAS and other readily biodegradable surfactants in rivers was determined to be in the range of 1–5 h, while the calculation model used in the EU risk assessment process assumes a value of 360 h [682].

10.4.3. Assessment of Environmental Effects

The impact of chemical substances to environmental systems can be different and may also include indirect effects, for example eutrophication of water due to a nutrient function of the substance, or remobilization of heavy metal ions. However, the most important aspect to be evaluated in the environmental risk assessment is the ecotoxicity of substances, i.e., the toxic impact to organisms living in the individual environmental compartments. Of course, it is not possible to test all these organisms in the laboratory in terms of their sensitiveness to the chemical. However, a number of internationally accepted and standardized test systems exist, which cover the different trophic levels of the aquatic food chain: starting from the algae as representatives of the plants, the plant-feeding animals, represented by the daphnia while the fish stand for higher trophic levels. Finally, the bacteria close the carbon cycle in the aquatic ecosystem due to their degradation activities (Fig. 128). In the terrestrial environment, too, the ecosystem has a similar structure, consisting of producers (plants), consumers (animals), and destruents (bacteria, fungi).

As in the case of degradation tests, there is a sensible hierarchy of ecotoxicity tests, starting with relatively simple acute toxicity tests which allow a first general evaluation; these are followed by more sensitive and more expensive chronic or subchronic tests which have a higher predictive value for the practical situation. In any case, the objective of the tests is to find out a relationship between the concentration of the test substance and the ecotoxicological effect. Therefore, the test organisms are exposed to different concentrations of the chemical under defined test conditions, and the effects are evaluated by comparison with benchmarks (without addition of the test substance).

10.4.3.1. Basic Ecotoxicity Tests (→ Chemical Products: Safety Regulations, Section 3.1.2; → Ecology and Ecotoxicology, Section 3.2)

The base set of ecotoxicological information of a chemical is obtained from acute tests on fish and daphnia and from an algal toxicity test (Table 50). Acute toxicity tests determine the lowest test concentration leading to death (fish) or immobilization (daphnia) of all tested organisms (LC_{100}/ EC_{100}). On the other hand, also the highest concentration showing no acute effect is experimentally determined (LC_0/EC_0). The acute toxicity is usually expressed by the LC_{50}/EC_{50} values, which can be calculated from the experimental LC_0/EC_0 and LC_{100}/EC_{100} data. The acute fish test is mainly conducted according to the pertinent OECD Guidelines [683] with zebra fish in a 96-h test. The acute daphnia test is also standardized [683] and has a duration of 48 h. The algal toxicity test differs from the previous tests, as the test criteria are based on the growth rate of the algal cells and the algal biomass formed within the 72- or 96-h incubation period [683]. Since this test not only covers the test organisms exposed at the beginning of the test but also the following generations of algae it is a chronic test determining the EC_0 and

Table 49. Stepwise environmental risk assessment process exemplified on a detergent-based surfactant (LAS)

Test hierarchy	Exposure analysis		Effects assessment			PEC/PNEC
	Basis	PEC	Basis	Extrapolation factor	PNEC

EC_{50} of algal growth (which is different from an acute algicidal effect). Despite the qualitative differences between the acute fish and daphnia tests and the chronic algae test, the LC_{50}/EC_{50} values from these three tests form the ecotoxicological criteria for the classification and labeling of substances as "dangerous for the environment" in the European Union [693]. At the same time also the environmental effects assessment for the preliminary determination of the PNEC takes reference to the lowest, i.e., most toxic LC_{50}/EC_{50} value from these tests [682]. The data from this set of three ecotoxicological characteristic values is also required when a new chemical is to be notified according to the chemical laws in EU member states [694].

Although not contained in the discussed ecotoxicological base set, the determination of the acute (e.g., bacterial respiration inhibition test [695]) or chronic (e.g., bacterial cell growth inhibition test [696]) toxicity to bacteria has a high ecological relevance for the practical situation. The chronic bacterial toxicity is measured during an 18-h incubation period using a *Pseu-*

NOEC = No observed effect concentration
LC/EC = Lethal/Effect concentration

domonas putida shake-flask culture and determining the rate of cell multiplication. The same bacterial species or an activated sludge culture is employed in the acute test measuring the influence of the test chemical on the oxygen consumption (respiration) rate of the bacteria. The EC_0 of this test has a high predictive value for the beginning toxicity of a substance to the purification performance of a biological sewage plant [697]. Information on the basic ecotoxicological data of a chemical product as well as the environmental classification (EU classification [693], Water Hazard Class in Germany [698]) is usually provided from the pertinent safety data sheets.

10.4.3.2. Subchronic and Chronic Ecotoxicity Tests

Information on long-term ecotoxicological effects at concentration levels fairly below their acute toxicity can be gained from standardized subchronic and chronic tests with the same test organisms also used in acute tests. This type of tests aims at determining the no observed effect concentration (NOEC), i.e., the highest tested concentration that does not exhibit any effect (vs. a benchmark). The criteria for assessing effects in the subchronic fish test (test duration 3–4 weeks) are not only lethality but also changes in growth, weight, behavior, etc. In the subchronic early life stage fish test with trout (OECD 204, test duration 90 d) [683] the influence of a compound on the most sensitive life stage of the fish is tested, because the development of juvenile fish from fertilized spawn is used as criteria. The 21-d daphnia reproduction test (daphnia life cycle test, OECD 202) [683] determines the number of new daphnids produced within the test period, and thus also covers the most sensitive life processes like growth, maturation, and reproduction.

10.4.3.3. Biocenotic Ecotoxicity Tests

While the discussed test systems are single-species tests, the biota in an environmental compartment form a biocenosis with many and complex interactions. Thus, the issue must be addressed whether a single-species NOEC is suitable to allow such biocenotic implications to be assessed. Laboratory tests also exist for biocenotic effects where a self-developing biocenosis of microorganisms, algae, unicellular protozoans, and small metazoans (rotifers) represents the "test organism" [699]. The possible impact of a chemical is determined by biological analysis of the qualitative and quantitative composition of the species developing within the test period. Examples of such tests are the microcosm test and the river flow simulation test [699]. Test

results obtained in such complex systems indicate that biocenoses are not significantly more sensitive to toxic substance influences than single species used in standard chronic/subchronic tests [700].

10.4.3.4. Bioaccumulation

Bioaccumulation or bioconcentration describes the fact that a compound is enriched in the living organism to concentrations higher than that prevailing in the surrounding milieu. Experimentally, bioconcentration is determined in relatively costly tests with fish or other aquatic organisms. These organisms are exposed to a very low concentration of the test substance and the increase of the substance in the organism in the time course is analytically monitored. The bioconcentration factor (BCF) describes the ratio of the substance concentration in the organism and the surrounding medium after attaining a steady state. The BCF can also be calculated from the quotient of the substance uptake (k_1) and elimination (k_2) rate constants; the latter is determined in the depuration phase of the experiment after transfer of the exposed organisms to substance-free water. The most widely used bioaccumulation test is the flow-through bioaccumulation fish test (OECD 305) [683].

Because of the demanding analytical requirements with regard to the sensitivity and specific detection of a compound in the test organism, e.g., in a fish homogenate, in most cases the physicochemical properties of the test substance or quantitative structure–activity relationships (QSARs) are used for the bioaccumulation assessment. The descriptor mostly used for the bioaccumulation potential is the partition coefficient of a substance in a two-phase system of water and octanol (P_{ow}). The P_{ow} can be determined experimentally [683] or by calculation [701]. Substances having a BCF ≥ 100 or a log $P_{\mathrm{ow}} \geq 3$ are considered as significantly bioaccumulating and are to be classified as "dangerous for the environment" if their ecotoxicity is also high (EC/LC$_{50}$ ≤ 10 mg/L) [683]. However, it has to be borne in mind that the P_{ow} is not generally suitable for prediction of the real bioaccumulation behavior of chemicals: it is not applicable to ionic substances and surfactants [683] and does not take into account the manifold biotransformation processes in living organisms [702].

10.4.4. Process of Environmental Risk Assessment

The exposure and effects assessment implies a hierarchy of methods starting with simple standardized basic tests up to exacting simulation tests and monitoring studies. All these investigations aim at conclusively predicting the environmental concentration (PEC) and a reliable no effect concentration (PNEC). The PEC and PNEC data generation is therefore a stepwise process. Depending on the outcome of the PEC/PNEC comparison it can be decided whether or not the PEC prognoses derived from simple but stringent (screening) tests are sufficient or whether data from more realistic (simulation) tests or monitoring data is required. A similar hierarchy of the predictive value of the data is implemented in the effects assessment by the use of application (safety) factors to derive the PNEC from acute LC/EC$_{50}$ data and chronic NOEC data, respectively (see Table 49). It should be noted that the chronic toxicity test data of chemical substances already imply the increased body burden resulting from a potential bioconcentration so that no additional safety factors need to be applied for the PNEC derivation.

These principles form the basis of the European environmental risk assessment process described in Technical Guidance Documents [682]. Environmental risk assessment is an iterative process which can be stopped when the PEC/PNEC ratio is ≤ 1, which indicates the environmental safety of the chemical ("no further information/tests required"), or when all possibilities to further improve the predictive value of the data are exhausted. Risk management measures are to be taken when a PEC/PNEC ratio > 1 indicates a risk for the environment [680, 681].

According to the three-tiered process described in Section 10.4.2.4 the environmental risk of key surfactants used in detergents (LAS, alcohol ether sulfates, alcohol ethoxylates, soap) was evaluated. The LAS example (Table 49) indicates that compounds with a high environmental relevance such as detergent components often require the information even from the highest

tier to reach PEC/PNEC < 1. In the end, this risk assessment showed that the most prominent surfactants in detergents are safe for the aquatic systems in spite of their high input to the environment [689, 690].

10.5. Ecological Characterization of Main Detergent Ingredients

10.5.1. Surfactants

The surfactants are the category of detergent ingredients with the highest ecological relevance due to their high consumption figures and their potential ecotoxicological impact connected with their surface-active properties. This relevance is reflected by the fact that the two most important surfactant groups, the anionics and nonionics, are subjected to legal regulations regarding their (primary) biodegradability (see Section 10.3.2). Strictly speaking, also the second main criterion for the environmental risk assessment, the ecotoxicological behavior is included therein because the primary biodegradation of surfactants and the loss of their high aquatic toxicity are normally concomitant processes. Hence, sometimes the primacy of biodegradation is emphasized since a fast and complete (ultimate) biodegradability is the best prerequisite to exclude long-term effects in the environment.

10.5.1.1. Anionic Surfactants

The oldest and largest-volume anionic surfactant worldwide is soap. However, the superiority of synthetic anionic surfactants in terms of detergency performance considerably reduced the relevance of soap in detergents in many countries. Instead, branched-chain TPS and its successor LAS have played the most important role as detergent surfactants. The poor biodegradability of TPS became evident in many rivers and sewage plants in the late 1950s and is also recognizable from the poor results in standard primary and ultimate biodegradability tests, as shown in Table 51 (see Section 10.3.1). Unlike TPS, LAS not only fulfills the legal requirements of the European detergent legislation but is also evaluated as "readily biodegradable" in the OECD 301 tests on ultimate biodegradability (Table 51). Also in the continuous activated sludge test (OECD Confirmatory Test) a high elimination result of about 95 % MBAS removal was found, which is still lower than the > 99 % removal measured in real sewage treatment plants [684].

The success of the measures to improve the environmental compatibility of detergent surfactants can be impressively demonstrated by the results of a systematic monitoring program conducted by the Henkel company in the river Rhine in Germany since 1958 and in some of its tributaries [678, 679, 703 – 705]. Based on the MBAS analytical method, the usage of TPS in detergents is recognizable as a continuous and steep increase of the MBAS loads and concentrations (Fig. 129); the maximum concentration detected in the Rhine was 0.72 mg/L MBAS in the fall of 1964 while concentrations of even more than 1 mg/L were observed in its tributaries [703]. The replacement of TPS by LAS in 1964 marked the turning point: the MBAS values decreased continuously from then on in spite of the fact that surfactant consumption increased by 80 % from 1963 to 1975 [703].

A second reason for this positive development was the construction of biological sewage treatment plants. In highly populated areas such as Germany such technical measures are a prerequisite for a sufficiently effective reduction of the organic load present in sewage prior to entering receiving waters.

Based on the experiences from the detergent problem of the early 1960s, the development of new detergent surfactants has always been a search for improvements in terms of both their detergency performance and the reduction of the environmental impact. Besides the legally required primary biodegradability, the ultimate biodegradability behavior today is in the focus of the ecological safety assessment of surfactants used in laundry products. As shown in Table 51, there are a number of anionic surfactants which exhibit excellent ultimate biodegradability in the OECD 301 tests. This underlines that the high removal rates determined in model sewage treatment plants are mainly due to mineralization (carbon dioxide formation) and assimilation (biomass formation). Furthermore, it

Table 51. Biodegradation data of surfactants

Surfactant	Primary biodegradation			Ultimate biodegradation

could be shown by comprehensive investigations based on metabolic studies with radiolabeled model surfactants, or on the "test for recalcitrant metabolites", that all major anionic surfactants are biodegraded without the formation of any poorly biodegradable intermediates [706]. Surfactants exhibit a distinct adsorption behavior onto suspended solids in sewage or surface waters that cause transportation of a significant portion of these chemicals into anaerobic environmental areas (see Section 10.4.2). Thus, surfactants which have proved their ultimate biodegradability in aerobic and anaerobic environments meet a very high standard of ecological safety, as they are biodegradable under all environmental conditions. Table 51 shows that the sulfated anionic surfactants (alcohol sulfates, alcohol ethersulfates) are anaerobically degradable in contrast to the sulfonated materials (LAS,

Figure 129. Changes of the anionic surfactant load (MBAS/LAS) in the river Rhine 1958–1999 (sampling site: Düsseldorf-Himmelgeist, Germany)

secondary alkane sulfonates, methyl ester sulfonates).

The second general essential criterion for the environmental risk assessment of chemicals is the effects assessment (see Section 10.4.3). The ecotoxicological behavior of the major detergent surfactants is very well investigated and documented involving acute, subacute/chronic, and biocenotic tests [689, 690]. Table 52 gives an overview of some ecotoxicological standard data of surfactants used for their evaluation according to the EU classification "dangerous for the environment" [693]. The comparison of the data reveals the marked aquatic toxicity of the surfactants with EC/LC_{50} values being predominantly in the range of 1–10 mg/L. This is a concentration range which could be achieved in surface waters if the surfactants were not biodegraded beforehand [707]. In reality, the concentrations of the most prominent detergent surfactants LAS are in the lower microgram per liter range even in small rivers receiving the effluents of biological sewage treatment plants [691, 708], while rivers receiving effluents from mechanical sewage treatment plants show LAS concentrations in the range of 500–600 µg/L [708]. It may therefore be concluded that the biological treatment of wastewaters is the decisive prerequisite for excluding an acute ecotoxicological impact of surfactants on surface waters' biota. Since an environmental safety assessment must take into account particularly long-term effects, predicted no effect concentrations derived from subacute and chronic toxicity data are more reliable than acute toxicity data. The no observed effect concentrations obtained in these tests with fish, daphnias, and algae are in the range of about 0.1–1 mg/L, i.e., one order of magnitude below the acute toxicity levels [689]; also the biocenotic NOECs determined in microcosm or mesocosm tests with anionic surfactants such as LAS and fatty alcohol sulfates [689, 700] are in the same order of magnitude. From information on the long-term ecotoxicity of key anionic surfactants a PNEC has been calculated, being 250 µg/L for LAS and 400 µg/L for alcohol ethersulfates [690]. Taking the discussed LAS concentration levels (PEC) into account it can be concluded that LAS and all other surfactants with a comparable ecological profile (readily biodegradable, ecotoxicological properties similar to LAS) will yield a ratio of PEC/PNEC $<$ 1, i.e., are safe to the aquatic environment [690].

The bioaccumulation behavior of surfactants in general was tested in several investigations that were mainly conducted using radiolabeled test materials [709]. While in some cases a bioaccumulation in fish can be definitely excluded (e.g., alcohol sulfates), in other cases only the bioconcentration of the radioactivity in the piscine body was determined without differentiation between the parent compound and the biotransformation products. A detailed investigation of the bioconcentration behavior of sev-

eral *n*-(*p*-sulfophenyl)alkanes, i.e., constituents of LAS, revealed that these chemical structures are not or only moderately bioaccumulative not the least due to the action of biotransformation processes [710].

10.5.1.2. Nonionic Surfactants

Alcohol Ethoxylates. Nonionic surfactants of the alcohol ethoxylate type are contained in almost all detergents and cleansers (see Section 3.1.2.1). Alcohol ethoxylates with a linear or single-branched alkyl chain are highly biodegradable. As shown in Table 51, they easily fulfill the legal requirements of a minimum primary biodegradability of 80 % BiAS removal and are "readily biodegradable" in the OECD tests on ultimate biodegradability. Alcohol ethoxylates are also bio-degradable under anaerobic conditions, thus providing all prerequisites for their fast and complete removal from the aquatic environment. The residue-free biodegradation of AE has been shown in the metabolite test [686] as well as in detailed investigations of the biodegradation pathways of these compounds [711, 712]. Consequently, also the elimination rates of alcohol ethoxylates in model plants (Table 51) and in real sewage treatment plants are very high (> 99 % [684]) and allow an environmental concentration (PEC) of a few micrograms per liter in receiving waters to be predicted. These figures are considerably lower than the BiAS concentrations determined in the river-monitoring programs of Henkel (10–100 µg/L [678, 704]). These differences are probably due to the insufficient specificity of the BiAS analytical method [713].

The ecotoxicological profile of AE has also been very well investigated. Their acute aquatic toxicity data are in the same order of magnitude as those of the anionics, although their algal toxicity seems to be more pronounced frequently (Table 52). The comprehensive set of available acute, chronic, subchronic, and biocenotic ecotoxicity data on alcohol ethoxylates was used in a recent environmental risk assessment study to derive a PNEC for alcohol ethoxylates [689]. The PEC/PNEC comparison led to the conclusion that this most prominent class of nonionic surfactants is safe to the aquatic environment [690]. Further support for this evaluation comes from comprehensive bioaccumulation studies showing that these surfactants are metabolized intensively in the piscine body [714].

Alkylphenol Ethoxylates. Another relevant group of nonionic surfactants still being used in some countries are the alkylphenol ethoxylates (see Section 3.1.2.2). In contrast to alcohol ethoxylates they show some ecological properties which have made their environmental compatibility questionable. Nonyl- and octylphenol ethoxylates have a highly branched alkyl chain which is an obstacle for microbial degradation. Thus, these surfactants are not readily biodegradable although they fulfill the legal requirement of > 80 % BiAS removal (Table 51). In winter conditions, however, even this primary biodegradation is relatively slow, so that foam problems in sewage treatment plants have been observed [715]. The major ecological reservations came from the fact that in the primary degradation process poorly biodegradable intermediates are formed which are even more toxic than the parent surfactant [716]. These intermediates (alkylphenol + 1–3 EO units) are poorly water soluble and are adsorbed strongly on sewage sludges. During the anaerobic treatment of these sludges in digesters alkylphenol is formed by splitting off the residual EO units. This metabolite shows an even increased aquatic toxicity [716, 717]. These findings led to a ban (e.g., in Switzerland in 1986) or voluntary renunciations (e.g., in Germany in 1987) of alkylphenol ethoxylates in laundry products. Since 1992 a PARCOM recommendation has existed to phase out alkylphenol ethoxylates in household laundry products by 1995 and in I& I cleaning products by the year 2000.

Alkylpolyglycosides. Developments towards more efficient and better environmentally compatible products are steadily in progress, also in the field of the nonionic surfactants. One interesting and promising example is the class of alkylpolyglycosides (see Section 3.1.2.6) These surfactants feature ready and complete ultimate biodegradability in aerobic and anaerobic environments (Table 51) [718]. Also, alkylpolyglycosides exhibit very low acute, subacute, and chronic toxicity data within the effect concentration range typical for surfactants (Table 52). A very conservative environmental risk assessment conducted on the basis of these data showed that this surfactant class is safe for the aquatic and terrestrial environment [718].

10.5.1.3. Cationic Surfactants

The cationics are the smallest of the three main surfactant groups (Table 45). They are not contained in usual detergents, but represent the active agent in fabric softeners (see Section 3.1.3). Until the beginning of the 1990s, ditallow dimethyl ammonium chloride (DTDMAC) was the most important cationic softener, with a market share of about 80 % [149] (see Section 3.1.3). This surfactant is almost quantitatively eliminated from sewage, as illustrated by the high elimination rates in model sewage treatment plants (columns 3 and 5 in Table 51). This is mainly due to adsorption onto sewage sludge, whereas its biodegradation is slow. As yet, cationic surfactants are not subjected to legal biodegradability requirements, although a group-specific analytical method exists to follow the primary biodegradation by measuring the decrease of the disulfine blue-active substance (DSBAS) [719].

Generally, degradation of cationics in usual screening tests is poor, maybe due to the fact that their bactericidal properties may prevent bacterial growth at the test concentrations required from the analytical point of view. However, even application of very low concentrations (< 1 mg/L) of ^{14}C-labeled DTDMAC did not result in substantial $^{14}CO_2$ formation under screening test conditions, and this indicates a poor biodegradability of DTDMAC even at concentrations that do not adversely affect bacterial growth. Results from activated sludge studies tend to be ambiguous due to the difficulty in distinguishing between elimination by adsorptive processes and real biodegradation. Analytical determinations of the residual amount of the parent DTDMAC present in the activated sludge of an OECD Confirmatory Test indicated that a major part of the elimination was due to (primary) biodegradation [720]. The strong adsorptivity of DTDMAC, its very slow aerobic biodegradability and its nonbiodegradability under anaerobic conditions resulted in relatively high concentrations of this surfactant in digested sludges [721]. These properties and findings in combination with the relatively high ecotoxicity of DTDMAC in standard tests (Table 52) triggered the development of alternative cationic

surfactants exhibiting more favorable ecological characteristics.

Today, the fabric softener market in industrial countries has virtually completely switched to new cationic surfactants. The major active ingredients in softeners are now esterquats (e.g., EQ, DEQ, DEEDMAC, see page 50). Esterquats are readily biodegradable under aerobic and anaerobic conditions which favors a high elimination rate in sewage treatment plants. This is attributed to genuine biodegradation (Table 51). Although the test for detecting recalcitrant metabolites is not applicable to strongly adsorbing compounds such as cationics, in-depth investigations of the degradation behavior of triethanolamine-based [149] and other esterquats [150, 722] have clearly indicated that these molecules are completely and ultimately biodegradable in the environment. The comparison of the ecotoxicological data of DTDMAC and the EQ esterquat (Table 52) points out the favorable ecological properties of the latter group of cationic surfactants. Although DTDMAC has not proved to be a risk for the aquatic environment according to the PEC/PNEC concept [723], it is even more evident that the use of esterquat cationics in fabric softeners does not have any negative impact to aquatic life.

10.5.2. Builders

As discussed in Sections 9.1.2 and 10.3.4, the complexing agent sodium triphosphate had been the main builder in almost all detergents in Europe, USA, Japan and other countries for a long time. Today, phosphate-free detergents are mainly based on builder systems consisting of the inorganic builders zeolite A and soda ash, and organic cobuilders such as polycarboxylates and/or citrate [166].

10.5.2.1. Zeolites

The major breakthrough with respect to phosphate-reduced and nonphosphate detergents was the development and introduction of inorganic water-insoluble sodium aluminum silicates of the zeolite A type. The ecological behavior of this ion exchanger had been investigated in a comprehensive research program that was started in 1973. It covered laboratory tests and field trials conducted by experts from industry, water authorities, and academia [724]. It was shown that no excessive sedimentation of the insoluble particulate matter occurred in the household sewer systems and communal sewage systems. A major part of the load of zeolite A (about 60 %) is already eliminated in the mechanical stage of sewage treatment plants (sand trap and primary settler) while total elimination is around 95 % after passing the biological stage and the secondary settler. Although the mass of the sewage sludge is increased due to zeolite, no negative effects on the purification performance of the activated sludge and on the anaerobic amenability of the sludge in the digester was found; no decreased retention of heavy metals in sewage plants has been detected in the presence of zeolite either. Investigations in the 1990s showed that zeolite A is quickly transformed into an extremely insoluble amorphous complex of basic calcium aluminum silicate phosphate under usual sewage treatment plant conditions [725].

Although only about 5 % of the zeolite A present in raw sewage will pass the sewage treatment plant, it was necessary to investigate all possible effects on the biota in receiving waters. Acute and long-term toxicity to fish and daphnia proved to be very low ($EC_0 > 250$ mg/L), while a growth-inhibiting effect on algae could be observed at concentrations > 10 mg/L in nutrient-poor culture media. This effect is, however, without any practical relevance because it is due to ion-exchange by zeolite A and the resulting depletion of essential trace elements in the test vessel [726]. In practice, zeolite A will never reach oligotrophic water bodies alone but only in conjunction with other nutrients in treated or untreated effluents. Long-term ecotoxicity data from fish (early life stage test) and daphnia (21-d reproduction test) revealed NOEC values of 87 mg/L and 37 mg/L, respectively [727].

Since no suitable analytical methods are available to determine zeolite concentrations in river water, calculations of the PEC were made by taking into account the consumption figures, elimination rates in sewage plants, and a river dilution factor of 10. Such a rough estimation leads to river water concentrations of 150–300 µg/L decreasing to 57 µg/L if a half-life of 1–2 months [728] is taken into account [725]. These

figures prove the environmental safety of zeolite A since the PEC is far below the PNEC.

10.5.2.2. Polycarboxylates

Phosphate-free detergents require cobuilders in addition to zeolite–soda ash to achieve comparable performance to STP [166] (see Section 3.2.4). By volume, the most important organic cobuilders are polycarboxylates, i.e., high-molecular mass ($M_r \leq 100\,000$) homopolymers of acrylic acid or copolymers of acrylic acid and maleic acid (Table 45). These water-soluble polyelectrolytes form sparingly soluble coagulates with excess calcium ions and adsorb on solid surfaces [729]. Based on these properties, polycarboxylates are eliminated to a high extent (> 90 %) in mechanical-biological sewage treatment plants [729, 730]. The contribution of biodegradation to this effective elimination process is minute. Polycarboxylates are poorly biodegradable except for the low molecular constituents ($M_r \leq 1000$) as was shown by investigations using ^{14}C-radiolabeled model compounds. On the other hand, polycarboxylates in real-life concentrations have proved to be without influence on the operation of sewage plants. They exhibited no adverse effects on the biological activity of sludge bacteria, the settling behavior of the sewage sludges, and heavy metal retention in laboratory tests and in a field trial [729]. Large amounts of polycarboxylates in sewage sludges do not influence the degradation process and the polycarboxylates are not redissolved in sludge digesters [729, 730].

Similarly comprehensive studies regarding fate and effects of polycarboxylates were conducted for the environmental compartments of surface waters and soil. These studies have shown that neither significant biodegradation nor heavy metal remobilization from the sediments is to be expected at relevant river concentrations (< 0.1 mg/L) [729, 730]. Due to the low ecotoxicity of polycarboxylates concluded from results of standard acute and long-term tests (acute EC_{50} > 200 mg/L, fish embryo larvae test NOEC = 40 mg/L, algal growth NOEC = 32 to > 200 mg/L, daphnia NOEC = 1.3–350 mg/L) a negative influence on the biota in surface waters can be excluded. The low no-effect concentrations within the broad range of the NOEC values observed in the chronic algae and daphnia test are connected with the precipitation of the polymer in the test system, i.e., with physical effects [730]. Bioaccumulation of polycarboxylates can be excluded because of their water solubility ($\log P_{ow} < -4.2$) and their high molecular mass.

Polycarboxylates will enter the terrestrial compartment when sewage sludges are used for agricultural purposes. The high-molecular polymers are retained in the top layer of the soil, as shown by lysimeter tests; the more mobile low-molecular fractions will hardly be present in real sludges because of their biodegradability and their less pronounced precipitation behavior [729, 730]. Thus, contamination of ground water by polycarboxylates can be ruled out. As expected, the ecotoxicity of these materials to terrestrial organisms is very low: the NOEC values in the plant growth test (> 200 mg/kg) and in toxicity tests with earthworms (1600 mg/kg) are orders of magnitude above the PEC_{soil} (< 0.1 mg/kg) [729, 730].

In spite of their proved environmental compatibility, the presently used polycarboxylates are still regarded as detergent components which are to be substituted as soon as efficient and biodegradable alternatives are available.

10.5.2.3. Citrates

Citrates are widely used in phosphate-free detergents and cleansers, especially in liquid formulations (Table 45). Since citric acid is a natural constituent and a common metabolite of most living organisms, it can be expected that its environmental behavior is very favorable. In fact, this compound is readily biodegraded in standard ultimate biodegradation screening tests and in continuous activated sludge tests [731]. Anaerobic biodegradation has also been proven [732], although only a small percentage of this water-soluble detergent ingredient will reach the anaerobic areas of the aqueous environment. Taking the citrate consumption in detergents and its excellent biodegradability into account, an influence of this weakly complexing agent on heavy metal remobilization in sludges and sediments can be excluded. The same positive conclusion is possible in regard to the ecotoxicological effects: citrate has low acute aquatic toxicity

values of $LC_{50} \geq 500$ mg/L (fish), $EC_{50} \geq 100$ mg/L (daphnia) and $EC_{50} \geq 1000$ mg/L (algae) [731, 732].

10.5.2.4. Sodium Carbonate (Soda Ash)

The inorganic compound soda ash plays an important role as a water-soluble builder and cobuilder in phosphate-containing and nonphosphate detergents. Although detergent-based consumption figures of soda ash are high (Table 45), no environmental impact is to be expected, because the ecotoxicological effects observed at high concentrations (daphnia $EC_{50} \geq 260$ mg/L, fish $LC_{50} \geq 200$ mg/L) are due to the resulting increase in the pH value of the test medium [731], which is irrelevant under real-life conditions.

10.5.2.5. Nitrilotriacetate (NTA)

In principle, NTA is an efficient builder and cobuilder in phosphate-free detergents. Its environmental compatibility was investigated in comprehensive studies [733]. Nitrilotriacetate was found to be ultimately biodegradable in aerobic conditions, although the degradation rate depends on temperature, concentration, and other ambient conditions. Heavy-metal complexes of NTA are degraded more slowly. The ecotoxicological data of NTA characterize this compound as weakly toxic to higher aquatic organisms (fish $LC_{50} \geq 100$ mg/L, daphnia $EC_{50} \geq 80$ mg/L). The NOEC of algal growth is in the range of 10 mg/L. In spite of these ecologically favorable characteristics concern arose from the strong complexing properties of NTA and, hence, the potential of heavy-metal remobilization. Due to uncertainties in regard to biodegradation rates of NTA under real-life conditions and its heavy-metal remobilization potential, it was recommended in Germany in the 1980s to use NTA only to a limited extent and to conduct further studies. The outcome of this successive program (1987–1990) is that NTA is readily biodegradable and is eliminated in sewage treatment plants to a high extent (95 %) irrespective of seasonal influences [734]. Heavy-metal removal from sewage is not impaired nor is a remobilization of heavy metals from river sediments to be anticipated below a concentration of 50 µg/L of NTA. Thus, NTA today is considerably more positively evaluated than in the past. Nevertheless, NTA is only used in minute amounts in detergents (Table 45), and it seems doubtful whether this compound will play a prominent role in the future as a detergent (co)builder.

10.5.3. Bleaching Agents (see Section 3.3)

10.5.3.1. Sodium Perborate

Sodium perborate decomposes during the washing process forming hydrogen peroxide and sodium metaborate. The water-soluble metaborate is not eliminated in wastewater treatment plants and may cause a considerable increase in the boron concentration in rivers. Although large regional variations exist due to geological conditions and degree of river pollution, the ratio of anthropogenic to naturally occuring boron in more closely investigated rivers in Germany was found to be up to 50 % in the river Rhine [703], about 70 % in the Neckar river [735], and considerably more than 100 % in the river Ruhr [736]. Nevertheless, a broad systematic study on the boron concentrations in German surface waters and drinking waters conducted in the mid–1970s [737] showed that boron concentrations in most rivers are below 0.25 mg/L and less than 0.1 mg/L in drinking waters. In small and heavily polluted rivers of Germany and other European countries higher concentrations up to 1 mg/L were found [737]. In the 1990s investigations on the boron content of drinking water in Germany showed that the concentrations had not changed significantly as compared with 1974 values [738]. Accordingly, more recent data from the river Rhine and its tributaries [678] have verified that the boron concentrations have not changed (rivers Rhine and Ruhr) or have decreased considerably (rivers Main and Neckar).

The ecotoxicological behavior of borate in water and soil has been studied comprehensively [739, 740]. The ecotoxicity of borate is relatively low. This is true for fish and invertebrates although the effective concentrations vary in a very broad range, depending on the individual studies. Fish LC_{50} values between 11 and 3400 mg/L are reported. Long-term toxicity data do

not indicate a pronounced ecotoxic action of borate either. NOEC values are clearly above a concentration of 1 mg/L [740]. However, literature data exists that indicate chronic effects towards certain aquatic organisms, e.g., fish, algae, or reed plants in the submicrogram per liter concentration range [731, 739, 740]. A critical reevaluation of these previously collected data in the light of more recent investigations showed, however, that the environmentally relevant no effect concentration in fresh waters is not lower than 1 mg/L [740]. Taking the reported river water concentrations of boron into account it is evident that boron does not constitute a problem for surface waters. However, the margin between the ecotoxicological no effect concentration and the environmental concentrations in the majority of rivers is relatively small.

With respect to the terrestrial toxicity of boron, a specific phytotoxicity towards certain agricultural plants exists, such as fruit trees, tomatoes, and vineyard stock. Therefore, it is not advisable to recycle boron-containing wastewater for irrigation purposes [739].

10.5.3.2. Sodium Percarbonate

Sodium percarbonate decomposes during the washing process forming hydrogen peroxide and sodium carbonate. Sodium carbonate is a water soluble mineral and ubiquitously present in the aqueous environment, because it is in equilibrium with carbon dioxide from the atmosphere and because of the presence of other dissolved mineral carbonates. Sodium carbonate has a very low aquatic toxicity (fish LC_{50} = 200–740 mg/L, daphnia EC_{50} = 265–565 mg/L) [731] which is attributable to the increased pH value at these high test concentrations. Thus, the use of sodium percarbonate as bleaching agent in detergents will not have any significant impact on the aquatic environment.

10.5.3.3. Tetraacetylethylenediamine (TAED)

Tetraacetylethylenediamine is the most widespread bleach activator used in laundry products (Table 45). In the washing process it is almost quantitatively perhydrolyzed to diacetylethylenediamine (DAED) and peracetate, the latter ultimately forming acetate. TAED and DAED dissolve well in aqueous alkaline solutions and have a low log P_{ow} [741]. The ready ultimate biodegradability of the two compounds has been shown in several tests [731, 741]. Accordingly, the elimination in sewage treatment plants is very high ($\geq$ 95 %) [741].

The ecotoxicity of TAED and DAED is remarkably low, since no effects were observed in the majority of tests, even at the highest concentration tested. For instance, the fish LC_{50} is well above 1000 mg/L and significant effects on daphnia and algae could not be observed at 800 and 500 mg/L, respectively [741]. Based on these biodegradation and ecotoxicological data it can be concluded that no adverse ecological effects will result from the use of TAED in laundry products.

10.5.4. Auxiliary Agents

Auxiliary agents are present in small amounts in many laundry product formulations. Nevertheless, their widespread use in these products results in considerable consumption figures (see Table 45) and, consequently, in a significant entry into the environment.

10.5.4.1. Phosphonates

Phosphonate compounds with more than one phosphonate group are suitable bleach stabilizers (see Section 3.3.4), because they are effective complexing agents and have additional chemical properties that support the washing process. Phosphonates have been well investigated with regard to their environmental behavior. They are poorly biodegradable under standard test conditions, although evidence exists that the chemically very stable C–P bond in phosphonates can be microbially attacked [742]. Nevertheless, phosphonates are not persistent in the environment, because they are subject to abiotic degradation in waters and in soil [742 – 744]. The degradation rate is strongly affected by the chemical composition of waters, e.g., the presence of metal ions like Fe^{3+}, and by sunlight. The degradation of HEDP is mainly based on photochemical processes [742,

743] while degradation of nitrogen-containing phosphonates seems to be a hydrolytic process that produces decomposition products which are, at least in part, accessible to biodegradation [742, 743]. Phosphonates are partially (about 50 %) eliminated in sewage treatment plants as shown in model experiments and field trials [742, 745]. In sewage plants having a phosphate precipitation stage the elimination of phosphonates is high (> 90 %) [745].

Phosphonates are strongly complexing agents which have the potential to affect the distribution and partitioning of metal ions in sludges, sediments, and soils. Laboratory and field studies showed no mobilization of heavy-metal ions in sewage sludges at phosphonate concentrations in the 2–10 mg/L range [742, 745]. Similar investigations on heavy metal release from river sediments made clear that the strong adsorption of phosphonates to sludges and sediments will prevent that metal ion remobilization occurs at environmentally relevant phosphonate concentrations of < 1 mg/L in wastewater and < 10 µg/L in surface waters [742].

The aquatic toxicity of phosphonates is low. The acute fish and daphnia LC_{50} values are > 100 mg/L [742]. Also, long-term NOEC data characterizes the phosphonates as unproblematic: subchronic/chronic studies on fish and daphnias revealed NOECs > 10 mg/L, i.e., orders of magnitude above the PEC levels [742]. Similarly to other complexing agents or ion exchangers, phosphonates, too, pretend to be relatively toxic to algae in standard tests. In fact, the algal NOEC was found to be in the range of 0.1–10 mg/L. However, there is clear evidence that this inhibition is due to the depletion of essential micronutrients for algal growth [742]. Ultimately, bioconcentration studies on two phosphonates (HEDP, ATMP) in fish [743, 744] proved that these chemicals do not bioaccumulate significantly.

10.5.4.2. EDTA

Ethylenediaminetetraacetate played an important role as a bleach stabilizer in the past. However, issues related to the environmental properties of this strongly chelating agent have led to a considerable decrease of its use in detergents. For instance, in Germany and some other European countries the use of EDTA in detergents ceased more than a decade ago. EDTA proved to be poorly biodegradable under environmental conditions although there is evidence that microbial degradation mechanisms exist [746]. In standard tests for ready and inherent biodegradability, this complexing agent indicated insignificant degradation rates and was not eliminated in a model sewage treatment plant (4 ± 2 % DOC removal in the Coupled Units Test) [731]. The insignificant elimination of EDTA in two-stage sewage treatment plants was confirmed in monitoring studies [747]. Thus, it is obvious that EDTA present in raw wastewater will enter receiving waters almost quantitatively. Accordingly, EDTA was found in rivers of Germany, the UK, Switzerland, and Austria in significant concentrations up to 50 µg/L [746]. At the same time similar concentrations of EDTA were detected in raw drinking water at sites where it is prepared from river water. This suggested that the processes normally employed for drinking water preparation do not eliminate low EDTA levels [747]. The influence of EDTA present in surface waters on the drinking water quality, its possible effects on remobilization of heavy-metal ions from sludges and sediments, and its deficiency of being adequately eliminated raised concerns about its environmental safety. This pushed activities towards replacing EDTA by phosphonates and NTA.

From an ecotoxicological point of view no critical aspects can be deduced. EDTA is not bioaccumulating and has a very low acute toxicity to fish and daphniae. LC/EC_{50} values are fairly above 100 mg/L [731, 746]. As expected, the algal growth NOEC in standard tests is considerably lower, i.e., in the range of 10 mg/L [731] which may be explained by the already discussed deprivation of trace metals in the test medium. On the other hand, stimulation effects of EDTA on algal growth are reported which could be explained by the photodegradation of ferric complexes to form less stable ferrous complexes with an enhanced bioavailability of growth-stimulating iron [746].

10.5.4.3. Enzymes (see Section 3.4.1)

Most detergents today contain enzymes, i.e., proteases, amylases, lipases, and cellulases. Being proteins, the ultimate biodegradation of enzymes in standard tests for ready biodegradability is high [731]. Investigations on the removal of protease in a model sewage treatment plant indeed showed a loss of proteolytic activity of more than 99 %. Of course, enzymes are also accessible to anaerobic degradation. The acute aquatic toxicity of enzymes is relatively low (fish LC_{50} = 25–350 mg/L, daphnia EC_{50} = 160 mg/L) [731]. Algal toxicity values are in the range of EC_{50} = 10–100 mg/L. The ecotoxicological effect concentrations of enzymes are better referred to enzyme activity rather than to weight.

10.5.4.4. Optical Brighteners (see Section 3.4.5)

Fluorescent whitening agents (FWA) in laundry products are mainly anionic diaminostilbene (DAS) or distyrylbiphenyl (DSBP) derivatives. They are hydrophilic water-soluble compounds having a high affinity to textile fibers and to particulate matter such as sewage sludges. A considerable portion of optical brighteners present in wastewaters is eliminated in sewage treatment plants (about 90 % in case of the most important stilbene derivative DAS 1, and about 50 % in case of DSBP, which is the major distyrylbiphenyl compound) [748]. This elimination is only due to adsorption but not to biodegradation since FWA are not readily biodegradable and seem only to undergo slow primary biological degradation [749]. In anaerobic digesters they are not biodegraded either, so that concentrations up to 1 g per kilogram of dry matter were found [749]. The portion of FWA not eliminated in wastewater treatment plants enters receiving waters and is exposed to daylight. The photodegradation of DAS 1 and DSBP was investigated in detail by experimental work and computer simulations [748]. As the kinetics of direct photodegradation is not only a function of the chemical properties of the FWA but also of the ambient environmental conditions (spectrum and intensity of daylight) the half life of DAS 1 varies from a few days to six months, whereas DSBP has a lifetime of a few hours. The photodegradation is essentially a primary degradation that forms a large number of products from DAS 1, while the degradation of DSBP follows a relatively simple path [748]. The triazinyl derivatives formed from DAS 1 during photodegradation are poorly biodegradable but weakly toxic in the acute fish test ($LC_0 > 97$ mg/L). The DSBP degradation products are predominantly accessible to biodegradation as shown in inherent biodegradability tests [748]. Recent monitoring data of the two major FWA species obtained in Germany and Switzerland revealed results that were well comparable with individual concentrations in the microgram per liter range in sewage, in the milligram per kilogram range in sludges and sediments, and in the nanogram per liter range in river waters [748].

The aquatic toxicity of FWA is low. Tests indicate fish LC_{50} values of > 320 mg/L (DAS 1) and > 70 mg/L (DSBP), respectively. The daphnia EC_{50} value for individual FWA is > 1000 mg/L. The algal toxicity is uncritical ($EC_{50} >$ 80 and > 10 mg/L, respectively) as well. The low ecotoxicity of FWA, which, in addition, do not bioaccumulate [749], is confirmed by the NOEC values determined for DSBP in the prolonged fish test (> 1 mg/L) and the three-week daphnia reproduction test (> 7.5 mg/L). The comparison of the PNEC deduced from these experimental results with the measured environmental concentrations does not indicate an environmental risk.

10.5.4.5. Carboxymethyl Cellulose

Carboxymethyl cellulose is a classical soil antiredeposition agent contained in some detergents. It is a water-soluble polymer which is only very slowly biodegraded [731, 750]. The resistance to biodegradation increases with the degree of substitution of free hydroxyl groups by carboxymethyl groups [750]. Thus, it is understandable that detergent-based CMC exhibits only poor results in ready biodegradability tests. Even in inherent biodegradability tests like the Zahn–Wellens test only a 40 % elimination value was found [731]. Also in the Coupled Units model sewage treatment plant CMC showed only a partial elimination with a 25 % DOC removal [731]. On the other hand, the polymer ex-

hibits the expected very low aquatic toxicity with EC_0 values > 1000 mg/L in the acute fish and daphnia test [731]. Based on these data CMC is not considered a detergent chemical impacting the environmental biota.

10.5.4.6. Dye Transfer Inhibitors

Dye transfer inhibitors are polymeric compounds that prevent the transfer of dyes from one laundry item to an other via the wash bath. A prominent representative of these compounds is poly(*N*-vinylpyrollidone) (PVP). Its ecological behavior is similar to that of CMC, i.e., PVP is poorly biodegradable in standard biodegradation tests and eliminated in sewage treatment plants only to a limited extent. The very low ecotoxicity of the polymer (chronic toxicity NOEC > 100 mg/L) on the other hand assures that no detrimental effects from PVP will result in the aquatic environment.

10.5.4.7. Fragrances

Fragrances are mostly present at concentrations < 1 % in almost all laundry products. Usually, they are very complex mixtures of numerous individual perfume components that differ in their chemical structure and therefore in their ecological behavior. Due to their volatility and adsorbing properties they have been considered hardly relevant to the aquatic environment. However, more recent studies have revealed that certain perfume compounds, e.g., musk xylene, can be detected in fish and river water, obviously due to a bioaccumulation process [751]. This nitro musk compound has a high log P_{ow} and is poorly biodegradable. Since this compound has also been detected in human adipose tissues and mother's milk [752], the detergent and cosmetic industry in some European countries (Germany, The Netherlands) has discontinued using this component in its products. This case exemplifies the necessity of a sufficient ecological knowledge on any detergent ingredient irrespective of whether it is contained in the product in high or very low concentrations. Presently, extensive investigation programs are under way to found a sound basis for the ecological evaluation of perfume ingredients used in detergents and cosmetics.

10.5.4.8. Foam Regulators (see Section 3.4.3)

Two key groups of chemicals used as antifoam agents are silicone fluids (polydimethylsiloxanes, PDMS) and paraffins (Table 45). Paraffins are accessible to ultimate biodegradation but the rate is strongly dependent on the chain length and the molecular mass, respectively. Polydimethylsiloxanes are not biodegradable but virtually quantitatively eliminated in sewage treatment plants due to their strong adsorptivity on sludges. PDMS that enter the terrestrial environment when sewage sludges are used for agricultural purposes are not persistent as they are abiotically decomposed in the presence of clay soils. Volatile cyclic products and linear water soluble siloxanols are formed which may undergo photolytic oxidative degradation [753]. PDMS and paraffins exhibit a low aquatic toxicity and have no bioaccumulation potential due to their polymeric properties. They will not have adverse effects on the environment.

10.5.4.9. Soil Repellents

The most important soil repellents in detergents are anionically modified polymers from terephthalic acid and poly(ethylene glycol). Due to their polymeric nature they are not readily biodegradable but, nevertheless, accessible to ultimate biodegradation under aerobic and anaerobic conditions. Based on results obtained in a static activated sludge biodegradation test system (OECD 202 B), the extent of elimination under sewage treatment plant conditions is expected to be very high. The ecotoxicity of these polymers is very low. They exhibit no acute toxic effects to fish, daphnids, and algae at the highest concentration tested (100 mg/L) which is clearly above their water solubility. Taking this data and the relatively low consumption figures (Table 45) into account it can be concluded that soil repellents pose no risk to the aquatic environment.

10.5.4.10. Dyes

Dyes are sometimes used in powder and liquid detergent products. The total usage of these complex compounds in detergents is very low (Table 45). Available ecological information on these materials from the producers' safety data sheets characterize them as poorly biodegradable and having low acute aquatic toxicity.

10.5.4.11. Sodium Sulfate

Sodium sulfate is used mainly as a filler in conventional powder detergents. The German consumption figure of this inorganic salt in detergents has decreased considerably within the last few years (1997: 100 100; 1999: 74 600 t/a [754]), mainly due to the growing market share of compact detergents. Sodium and sulfate ions are natural constituents of surface waters. Based on recent consumption figures (Table 45) and sulfate concentrations in several German rivers (30–160 mg/L), it can be calculated that the contribution of detergents to the sulfate load in rivers is less than 1 %. The aquatic toxicity of sodium sulfate is very low. The LC_{50} is in the range of $>$ 1 g/L [731]. Hence, regarding the mass balance and the ecotoxicity of this compound it is obvious that sodium sulfate from detergents does not represent a significant factor influencing the aquatic environment.

11. Toxicology

Detergents are products designed for everyday use; thus, they are found in large quantity in nearly every household. The home is quite unlike the industrial workplace: one cannot assume that every user of a household product plays strict attention to warning labels or recommended safety precautions. For this reason, any product offered on the market must insofar as possible be formulated so that it represents no significant or foreseeable health hazard, regardless of whether or not the product is properly handled. This in turn means that even at the earliest stages of raw material selection, great value should be attached to chemicals known to be harmless to humans following any realistic type of exposure.

The following types of exposure must be taken into account in assessing the risk presented by detergents and their components:

Skin contact (wash bath, residues remaining on laundered items, or exposure during manufacture)
Ingestion (accidents, especially with children, and trace residues in drinking water)
Inhalation (during production or use of powder detergents)

Extensive toxicological studies are required, and the results must be carefully weighed, taking into account the amount and stability of individual substances. Such studies should examine local effects (skin irritation, development of allergic reactions on contact, skin penetration), systemic effects (both acute and chronic), and potential hazards of a more subtle nature (mutagenicity, embryotoxicity, and carcinogenicity).

This chapter begins by examining the toxicology of the main detergent constituents, after which the properties of complete detergent formulations are explored. The approach is analogous to that followed in practice by a manufacturer in the course of product development.

11.1. Detergent Ingredients

11.1.1. Surfactants

Most of the biological properties of surfactants can be understood in terms of interactions occurring between surfactant molecules and such fundamental biological structures as membranes, proteins, and enzymes. Contact between a surfactant and a membrane leads to changes in membrane permeability, and in extreme cases, can even result in membrane solubilization. The most obvious potential consequence is interference with material transport and, ultimately, cell damage. A further danger is the fact that surfactants can significantly affect the resorption of other chemicals.

Proteins form adsorption complexes with both anionic and cationic surfactants. Complex formation is often a consequence of polar interactions between the hydrophilic residue of a surfactant and charged sites on the protein molecule, but hydrophobic interactions can also play a role. Such complex formation results in

protein denaturation, which in the case of an enzyme implies a reduction or even total loss of catalytic activity, corresponding to a change in metabolic function [755].

Nonionic surfactants are characterized by their lack of strongly polar functional groups. Thus, compounds of this class rarely cause protein denaturation. They can induce a limited amount of protein solubilization, but the concentrations required for the appearance of harmful effects are usually greater than those of ionic surfactants.

Transport through skin is an important consideration with respect to detergent ingredients, which tends to be quite low for anionic and cationic surfactants [756, 757]. Transport is greater for nonionic surfactants, but again the amount of material capable of entering an organism by this route is so low that it can be essentially disregarded as a potential hazard [758]. By contrast, both anionic and nonionic surfactants can be readily resorbed through the gastrointestinal tract following their ingestion, whereas the intestinal resorption of cationic surfactants is low [759]. Even absorbed surfactants are relatively harmless because they are rapidly metabolized, mainly by β- or ω-oxidation of alkyl chains and some cleavage of poly(alkylene glycol) ether linkages. Elimination occurs through the bile and the urine; significant accumulation within the body has never been demonstrated.

The ability of surface-active agents to emulsify lipids means that repeated or prolonged exposure to surfactant-containing solutions can cause damage to the lipid film layer that covers the skin surface. As a consequence, the barrier function of the lipids is impaired, leading to increased permeability and loss of moisture. This is evidenced by dryness, roughness, and flaking of the skin. Very prolonged exposure to concentrated surfactant solutions can lead to serious damage and even necrosis. Skin tolerance varies widely among the compounds making up each class of surfactants. Nevertheless, one can generalize that tolerance to surfactants tends to increase in the order cationic, anionic, nonionic materials.

Broadly speaking, all of the commercially relevant surfactants are well-tolerated in the concentration ranges applicable to detergent use [760, 761]. However, certain structure–activity relationships have been found. With nonionic surfactants, for example alcohol ethoxylates, skin irritation diminishes with an increasing degree of ethoxylation [762]. For anionic surfactants, the length of the alkyl chain is closely related to skin irritability. Thus, within a given homologous series, compounds containing saturated alkyl chains of 10–12 carbon atoms show the strongest effects [763].

The eye is much more sensitive than skin to damage by small amounts of surfactants. Anionic surfactant solutions with a concentration above ca. 1 % can produce minor eye irritation, although this is normally reversible [763]. Serious damage is likely only if the eye comes in direct contact with a concentrated surfactant solution and if this contact is not followed by immediate and intensive flushing with water.

Virtually all surfactants that are employed in detergents have been the subject of extensive investigation with respect to their allergenic properties. In no case has an increased risk of allergy for the consumer been demonstrated. A few isolated examples of sudden, multiple allergic reactions in connection with anionic surfactants (alkyl ether sulfates or α-olefinsulfonates) were later traced to impurities of 1,3-sultones and chlorosultones, compounds that have long been recognized as potent allergens and that can arise by bleaching of surfactants with hypochlorite at low pH [764].

The acute oral toxicity of surfactants is low; LD_{50} values normally fall in the range of several hundred to several thousand milligrams per kilogram of body weight [765]. The major detrimental effect of surfactants is damage to the mucous membranes of the gastrointestinal tract. High doses lead to vomiting and diarrhea. If a surfactant reaches the circulatory system, it can cause damage even in very low concentration as a result of interactions with erythrocyte cell membranes, ultimately resulting in destruction of the cells (hemolysis). Inhalation of dust or aerosol containing high concentrations of surfactants can interfere with pulmonary functions [766]. This interference can be partly attributed to interactions with the surface-active film of the vesicles of the lung [767].

The possibility of chronic toxicity has been a subject of intense investigation with members of all of the surfactant classes. Tests with experimental animals involving exposures for up to two years in dosage ranges of several thousand

parts per million have without exception shown complete safety [760, 761, 768]. Moreover, a number of investigations have been conducted over long periods of time with human volunteers. Substantial amounts of both anionic and nonionic surfactants were administered, but no serious side effects were discovered [765].

Neither long-term oral ingestion nor continuous skin exposure has ever suggested that surfactants within the three major groups possess carcinogenic activity [760, 769]. Similarly, surfactants can be regarded as completely devoid of both mutagenic [770] and teratogenic [760, 769] characteristics.

11.1.2. Builders

The most important substances in this category are sodium triphosphate, zeolite A, and sodium nitrilotriacetate (NTA).

Pentasodium triphosphate can be regarded as innocuous. Effects of triphosphate ingestion first become acute with dosages of several grams per kilogram of body weight, and even these manifestations are simply a result of localized damage caused by the high alkalinity of concentrated phosphate solutions [771].

Zeolite A has undergone intensive toxicological investigation and has been found to possess absolutely no acute toxicity. The compound is also tolerated well locally. No adverse effects are seen with eye tissue beyond those associated with the presence of any foreign body. Studies on chronic toxicity or carcinogenicity following oral ingestion have also shown zeolite A to be completely safe when used in detergents, even considering long-term use of the products. Inhalation of the material leads neither to silicosis nor to the development of tumors. Isolated reports of alleged carcinogenic activity have been associated with synthetic zeolites, but these have been shown to be related to the presence of natural zeolites possessing a fibrous morphology. The latter are indeed capable of inducing tumors, unlike zeolite A, which consists of cubic crystals. In summary, zeolite A appears to present no health risks [772].

NTA shows little acute toxicity with respect to both inhalation and oral ingestion. Moreover, the compound produces minimal adverse effects on the skin even after repeated exposure, and it has no sensitizing properties. NTA is readily absorbed through the gastrointestinal tract, but it is then quickly eliminated without being metabolized. Numerous investigations support the conclusion that NTA is not a mutagen. Results from animal studies have shown that repeated applications of large amounts of NTA can cause changes in the urinary tract, including tumor formation, but these changes seem to be due to alterations in the metabolism of certain divalent cations by interaction with the complexing agent NTA. This effect is not considered relevant to conditions likely to be found when NTA is used in detergents. The possibility cannot be excluded that use of NTA could lead to trace amounts in drinking water. Nevertheless, concentrations to date have never been found to exceed a few micrograms per liter, and toxicological data suggest that this presents no human health risk [773 – 778].

11.1.3. Bleach-Active Compounds

Sodium perborate and sodium percarbonate show only slight acute toxicity. Extensive contact with concentrated solutions can cause irritation to the skin and mucous membranes, but this is a consequence of alkalinity rather than a specific effect of the substances themselves. The rapid hydrolysis of the bleaching agent means that any physiological effects that are observed will be those of borates or carbonates, respectively. While it is true that these substances pass readily through the mucous membranes or through damaged skin surfaces, intact skin prevents excessive amounts from being absorbed. However, the intestinal tract is capable of admitting substantial amounts of boric acid, and the substance is considered lethal to adults at a dose of 18–20 g [779]. Studies have revealed reprotoxic effects in animals treated with borate [780]. However, with respect to the exposure situation of normal use of detergents a human health risk can be excluded.

11.1.4. Auxiliary Agents

Enzymes. The proteolytic enzymes employed in detergents are quite safe from a toxicological standpoint. Evidence of local skin ir-

ritation appears to be rare, as are systemic effects following ingestion. As with all proteins, however, human allergic reactions are possible. Indeed, exposure to industrial dust in the early days of the production of enzyme-containing detergents resulted in a number of asthmatic reactions among factory workers. This risk has been eliminated by drastic reduction in the enzyme concentration of industrial dust and by the introduction of coated enzyme granulates, prills, and extrudates.

The possibility that a consumer might inhale significant amounts of enzyme from detergent dust can be essentially excluded. Thus, the only plausible and relevant form of consumer exposure is skin contact in the course of dealing with hand-washable items. At one time a definite relationship was assumed between skin reactions and use of enzyme-containing detergents, but a large body of evidence now shows the contrary. It appears safe to say that the presence of enzymes does not contribute to skin irritation by detergents, nor does it lead to increased risk of allergenic reactions [781 – 783].

Fluorescent Whitening Agents. Much information is now available that supports the conclusion that the fluorescent whitening agents employed in detergents are safe materials. All studies on toxicity, teratogenicity, mutagenicity, and carcinogenicity are consistent in affirming that such compounds present no risk. Local tolerance of the substances is also good, and they display no tendency to cause sensitization. Moreover, long-term studies involving cutaneous application have failed to reveal any carcinogenic potential. Fluorescent whitening agents bind rather tightly to proteinaceous material; as a result, they are firmly retained by the upper keratin layer of the skin, ruling out any significant percutaneous transport. The correspondingly firm binding to textile fibers implies that risks of exposure by way of clothing can also be disregarded. In other words, all available toxicological and dermatological evidence supports the belief that low-concentration detergent use of fluorescent whitening agents presents no human health risk [784, 785].

11.2. Finished Detergents

Appropriate choice of ingredients has enabled manufacturers to assure the virtual absence of health risks associated with detergent use. Potential long-term and systemic risks, such as mutagenicity, carcinogenicity, allergy, etc., all are examined and eliminated in the course of the thorough evaluations that routinely accompany raw material considerations during product development. Nevertheless, the possibility remains that finished products could reveal harmful characteristics despite the safety of the raw materials. Acute toxicity and localized reactions are both potential areas of concern, because complex mixtures occasionally show behavior in these respects different from that predicted for the sum of the components.

In fact, the usual commercial detergents display only minimal acute toxicity. Oral ingestion leads usually to vomiting, and this may be accompanied by irritation of the mucous membranes of the gastrointestinal tract and diarrhea. Low toxicity and the fact that vomiting is virtually unpreventable after ingestion of large quantities of detergent essentially exclude any serious threat of poisoning through product misuse, even with respect to children.

Skin irritation is also practically ruled out for modern detergents, provided they are used as directed. Nevertheless, the surfactants that are present and the alkalinity of detergent solutions cause natural lipids to be removed from exposed skin, which can result in minor irritation. Most reported instances of skin irritation can be attributed to extreme levels of exposure coupled with inadequate skin care.

Similarly, no risks appear to be associated with the use of laundry and clothing that has been treated with modern detergents. Only very small amounts of the detergent components (e.g., surfactants, zeolites, fabric softeners) remain on the fabric after rinsing [786]. Of these minor remnants again only traces can be transferred to the skin, amounts well under the limits of local or systemic toxicity [786, 787].

11.3. Conclusions

The constituents of modern detergents can be regarded as toxicologically well characterized and

safe for the consumer. The occupational safety concerns that remain in the production process center around surfactants, alkaline components, and the local effects these elements can have on the skin and mucous membranes. Detergent enzymes present the potential for allergenic problems, but the risk is minimal if suitable protective measures are implemented.

From the standpoint of consumer protection, the standard commercial detergents are entirely safe. Even inadvertent misuse of the products can be expected to lead to only minor effects, which are readily reversible.

12. Textiles

A dominant characteristic of the current textile market is the large range of available products. Moreover, essentially all of the fiber types that are worked into textiles for everyday use lend themselves to washing with water — although not all fabrics and finished goods are equally able to withstand high wash temperatures, the alkaline medium, and vigorous mechanical action. Of course, articles that cannot be regarded as washable require dry cleaning; examples include wool suits and dresses, silk neckties, and various highly ornamented items made from a variety of different materials. Nevertheless, the overwhelming majority of fabrics and knitwear is washable and is washed — in some cases very frequently. Proper washing conditions vary from fabric to fabric, depending on a number of parameters.

Questions regarding washability and, in particular, choice of optimum washing conditions (e.g., selecting the proper cycle with an automatic washing machine), can no longer be resolved simply by determining what type of fibers is involved. Indeed, it has become increasingly necessary to take into account such factors as the types of dyes present and finishing operations to which a fabric may have been subjected.

Dyeing and Printing.

Dyes for Cellulosic Fibers. All cellulosic fibers (cotton, linen, viscose, etc.) resemble one another in their properties and can all be dyed with the same materials and by similar procedures. What follows is a description of the major types of dyes appropriate to these fibers.

Direct dyes are transferred onto the fibers directly from a hot dye bath. Materials that have been subjected to direct dyeing are quite capable of withstanding a gentle wash cycle at 40 °C, although subsequent treatment with special chemicals can further improve both wash- and water-fastness.

If a textile color is to withstand hot water washing (60 °C) and if a direct dye is to be used, the dye must be carefully selected and a special treatment (fixation) must be administered to increase fastness. Alternatively, dyes can be chosen that lend themselves to after-coppering. In any event, dyes must be chosen from the appropriate fastness grouping at the time of original dyeing.

If a dyed cellulosic fabric is to be subjected to particularly high demands for fastness, a dye of an entirely different type is commonly selected. Among these are vat dyes, reactive dyes, or dyes in the naphthol, phthalocyanine, or sulfur categories. Reactive dyes are capable of forming chemical bonds with cellulose molecules, which display exceptionally high degrees of water fastness.

Dyes for Wool and Silk. Only relatively few such dyes are sufficiently versatile for application to wool and silk. Wool is normally treated with acid dyes, at least in the absence of extraordinary requirements for fastness. Metal-complex dyes have been specially developed for the treatment of wool, and they possess unusually good fastness properties.

Dyes for Synthetic and Cellulose Acetate Fibers. Synthetic and cellulose acetate fibers are generally treated with disperse dyes or, in some cases, pigment dyes. The insoluble coloring agent present is subsequently fixed to the fabric with the aid of heat-setting resins.

The printing of textiles entails the use of essentially the same coloring agents that are employed in dyeing; a separate discussion of this process is therefore unnecessary. In any case, a crucial step in dying and printing of textiles is a special treatment to maximize color fastness. If the color fastness is insufficient, the dyes will severely fade upon washing. The lower the fastness, the more easily colors will fade, independent of the composition and ingredients of the detergents used. Low quality colored textiles may already fade when only water and mechanical action are applied to them.

Finishing. Consumers have come to expect fabrics emerging from washing with relatively few wrinkles. Wrinkles that remain should disappear quickly or easily be ironed off without the need for special treatment. Meeting these expectations has required manufacturers to develop special finishing methods involving the use of special resins. Appropriate water-soluble resin precondensates are applied to the raw fabric, which are induced to condense during a subsequent drying process.

With the assumption that washing is conducted under the proper conditions, resin finishing assures that the original crease angle is largely restored as the fabric dries, thereby eliminating the need for ironing. Furthermore, garments treated in this manner retain their form as they are worn. Resin-finished fabrics are frequently called permanent-press, easy-care, wash-and-wear, or no-iron fabrics.

Fabric finishes tend not to be permanent: the benefits they confer are gradually lost as a garment is subjected to repeated washing. Certain finishing characteristics can be restored by laundry aftertreatment aids, however, particularly softness, stiffness, or antistatic properties.

In some countries (e.g., the USA and Canada), flameproofing is another form of fabric finishing commonly applied to household goods. Items that have been so treated are generally identified by special labels. Strict adherence to manufacturer's washing instructions is necessary if lack of flammability is to be maintained.

A recent form of fabric finishing is the application of sun protection for special textiles such as garments for leisure, sports, and children's wear. Sun protection for fabrics is considered particularly valuable for regions with increased UV radiation due to ozone depletion in the stratosphere. Sun-protection finishings are commercially available, and are permanent and washfast [788, 789].

Washable Fabrics. Textile demand for washable fabrics in Europe (i.e., in the countries comprising the EU) for 1994 is outlined in Table 53 [790]. Three types of material can be seen to account for most of the sales: cotton (47 %), wool (9 %), and synthetic fibers (42 %). Attention is drawn to the fact that by far the largest part of synthetic fibers for domestic use is blended with natural fibers such as cotton and wool. Pure synthetic fibers are used only to a lesser extent for apparel and home furnishing textiles except upholstery and curtains. Table 53 also reveals the distribution of these fabrics over the principal categories of household washables.

In Western Europe, the proportion of white goods in a typical laundry has been quite constant since 1988. This trend is illustrated for Germany in Figure 130. These data can be extrapolated to reflect generally the situation in the European Community as a whole.

* Excluding Denmark, Ireland, and Greece.

it accounted for 35 % of total laundry in 1994 (see Fig. 131). The washable fabrics comprise home-washed domestic laundry including clothing, towels, bed sheets, etc. [791].

Washing Conditions. Washable woven and knitted fabrics are normally washed either in the household, in a launderette, or by a professional laundry. The distribution among the three varies widely from country to country. In Germany, for example, more than 90 % of household laundry is done at home, usually in a horizontal-axis drum-type machine. In Europe generally, wherever the percentage of households with washing machines is high, the fraction of the laundry done at home is also high. A major reason for this pattern is the substantial reduction of effort brought by the technological advances incorporated in current automatic washers. The process has become even simpler with the advent of wash-and-wear fabrics. The finishing work associated with a load of laundry currently entails little more than folding and putting away the washed and dried articles (Fig. 132).

Establishing proper washing conditions — temperature, time, mechanical input, wash liquor ratio, and detergent — requires consideration of the characteristics of each of the materials that make up a given article of laundry. For this reason, washability is a characteristic that can only be measured with respect to finished goods. However, conditions imposed during washing, drying, and ironing differ, depending on whether the process is carried out at home or in a commercial laundry. Differences occur in times required for washing and drying, the stress imposed in conjunction with hot-air drying, and the pressure and temperature associated with ironing.

Throughout Europe, white and colorfast cottons are usually washed with a heavy-duty detergent and a normal machine program, i.e., at 60–95 °C with a low wash liquor ratio and a standard amount of mechanical input. Cottons that are not colorfast are usually washed at 40–60°C, frequently with color detergents. Pastel coloreds often require the use of specialty detergents or heavy-duty detergents designed for colored fabrics; their main advantage is the absence of fluorescent whiteners and bleaching agents.

Woolens and silks are regarded as especially sensitive to washing conditions. In some cases, these fabrics must simply be accepted as nonwashable and submitted to dry cleaning. The surface of a wool fiber has a unique "scaly" construction; this peculiar morphology contributes to wool's characteristic tendency toward *felting*. This term is used to describe the appearance of wool after mechanical action has caused individual fibers to become entangled with one another. Wool can be washed much more successfully if it is first given a special treatment known as an

Table 54. Distribution of colored and white fabrics in the USA

Fabric color	Percentage			
(% white)	1993	1995	1997	1999
Only white (100 %)	18	17	18	17
Mostly white (75 %)	12	13	12	12
Mixed white (50 %)	21	19	18	18
Mostly colored (25 %)	16	17	16	17
Only colored (0 %)	33	34	36	36

Figure 132. Effort involved in the laundry process in Germany [792]
The reduction in energy expenditure accompanying various stages of technological development through the last 50 years is symbolized by the length of the black bars under the various pictures. The more automated the process and the more nearly the fabrics show "easy-care" ("wash and wear") characteristics, the less the effort required.

antifelting finish. Woolens and silks should always be washed at low temperature (maximum 30 °C), using a high wash liquor ratio and a reduced level of mechanical input. The detergent employed should be either designed for easy-care fabrics or else a product specifically intended for wool.

Synthetic fabrics made from regenerated cellulose fibers (e.g., rayon staple or artificial wool), require a wash temperature of 60 °C, but if sensitive colors are present, the temperature should be reduced to ca. 40 °C. A high wash liquor ratio is recommended, as is a limited amount of mechanical input. Cellulose acetate is generally washed at 40 °C.

Pure synthetics are best washed using a gentle program with a high wash liquor ratio. A heavy-duty detergent is considered appropriate, as is one designed for easy-care fabrics. In some cases a specialty detergent for colored fabrics is necessary (e.g., with uniformly colored pastels, when optical brighteners are to be avoided).

White polyamide fabrics can be washed at 60 °C, colored polyamide fabrics at 30 or 40 °C.

White polyester fabrics are washed at 40 or 60 °C, whereas colored polyesters can only withstand a wash temperature of 40 °C.

Knitware made of polyacrylonitrile is treated like wool, i.e., it is washed in cold water (or at a maximum of 30 °C). White polyurethane-containing undergarments can be washed at 40–60 °C, and colored items at either 40 or 60 °C, depending on the degree of colorfastness.

Many of the easy-care fabrics on the market consist of blends of two or more fiber types brought together as the material is woven or

Table 55. Washability of textiles

Fibers	White		Colored		Pastel colored	
	Temperature, °C	Bath ratio *	Temperature, °C	Bath ratio *	Temperature, °C	Bath ratio *
Natural fibers						
Cotton	95	low	40, 60, or 95 **	low	95 or 60	low or high
Linen	95	low	40, 60, or 95 **	low	95 or 60	low or high
Wool	cold, <30	high	cold, <30	high	cold, <30	high
Silk	cold, <30	high	cold, <30	high	cold, <30	high
Chemical fibers (cellulosics)						
Rayon staple	60	high	60 or 40	high	60 or 40	high
Acetate	40	high	40	high	40	high
Chemical fibers (synthetics)						
Polyamide	60	high	30 or 40	high	30 or 40	high
Polyester	30–60	high	30 or 40	high	30 or 40	high
Polyacrylonitrile	cold, <30	high	cold, <30	high	cold, <30	high
Polyurethane	40–60	high	40–60	high	40–60	high

* Low: bath ratio 1 : 5 and normal mechanical input; high: bath ratio 1 : 20 to 1 : 30 and decreased mechanical input.
** Colorfast items.

knitted. Such blends are treated like easy-care fabrics, using a high wash liquor ratio and gentle agitation. Recommended wash temperatures vary, depending on the nature and composition of the blend. In general, the recommended laundering conditions are those that apply to the major constituent. Wool/polyacrylonitrile or wool/polyester blends are always washed at low temperature (maximum 30 °C), whereas with permanent-press cotton/polyester blends, 60 °C is appropriate.

Items that consist of two or more types of fabric or yarn (e.g., linen tablecloths with wool embroidery, cotton shirts with polyamide piping, jackets with an easy-care exterior and a standard rayon lining, etc.) require different treatment than blended fabrics. The same applies to materials containing dyes of varying degrees of fastness. Such items must always be washed, dried, and ironed under the conditions applicable to the most sensitive fabric or color present, even if this fabric constitutes only a small portion of the whole. For example, a cotton tablecloth with a small amount of wool embroidery requires the same treatment as if it were made entirely of wool. Table 55 provides a summary of the washability of various fibers.

Care Labeling. The European Community (EC), acting in the interest of consumers, has developed a uniform and comprehensive system of care labeling for textile goods. This system has required the cooperation of textile fiber manufacturers, the textile and detergent industries, and representatives of the laundry and dry-cleaning trades. The results are illustrated in Table 56 [793]. Labels of the approved type are permanently affixed to items of clothing prior to sale, providing the consumer with a straightforward guide to proper washing and handling. The symbols themselves are internationally protected trademarks, the rights to which are held by the Groupement International d'Etiquetage pour l'Entretien des Textiles (GINETEX). The German trademark rights rest with the Arbeitsgemeinschaft Pflegekennzeichen für Textilien in der Bundesrepublik Deutschland, itself a member of GINETEX. The German organization also confers the right to use these symbols. No license fees are entailed, but the symbols must be used correctly and in their entirety, as specified in the appropriate guidelines. Improper use can lead to loss of the right to employ the symbols. Care labels must be understood merely as sources of advice; they do not in any sense represent evidence of product quality. Nevertheless, any label that appears must be appropriate to the item in question and must be legible and permanently affixed. In NAFTA countries care symbols used are nearly identical to those employed in the EC. Only in a few cases do they differ somewhat.

Table 56. GINETEX internationalcare labeling symbols

Washing

Symbol	Washing process
	– maximum temperature 95 °C – mechanical action normal – rinsing normal – spinning normal
	– maximum temperature 95 °C – mechanical action reduced – rinsing at gradually decreasing (cool down) – spinning reduced
	– maximum temperature 70 °C – mechanical action normal – rinsing normal – spinning normal
	– maximum temperature 60 °C – mechanical action normal – rinsing normal – spinning normal
	– maximum temperature 60 °C – mechanical action reduced – rinsing at gradually decreasing temperature (cool down) – spinning reduced
	– maximum temperature 50 °C – mechanical action reduced – rinsing at gradually decreasing temperature (cool down) – spinning reduced
	– maximum temperature 40 °C – mechanical action normal – rinsing normal – spinning normal
	– maximum temperature 40 °C – mechanical action reduced – rinsing at gradually decreasing temperature (cool down) – spinning reduced

Table 56. Continued

	– maximum temperature 40 °C – mechanical action much reduced – rinsing normal – spinning normal – do not wring by hand
	– maximum temperature 30 °C – mechanical action much reduced – rinsing normal – spinning reduced
	– hand wash only – do not machine wash – maximum temperature 40 °C – handle with care
	– do not wash – be cautious when treating in wet stage

Chlorine-based bleaching (hypochlorite)

Symbol	Process
	– chlorine-based bleaching allowed – only cold and dilute solutions
	– do not use chlorine-based bleach

Ironing

Symbol	Process
	– iron at a maximum sole-plate temperature of 200 °C
	– iron at a maximum sole-plate temperature of 150 °C
	– iron at a maximum sole-plate temperature of 110 °C – steam-ironing may be risky
	– do not iron – steaming and steam treatments are not allowed

Table 56. Continued

Dry Cleaning	
Symbol	Process
	– dry-cleaning in all solvents normally used for dry-cleaning — this includes all solvents listed for the symbol P plus trichlorethylene and 1,1,1-trichlorethane
	– dry-cleaning in tetrachloroethylene, monofluorotrichloromethane and all solvents listed for the symbol F – normal cleaning procedures without restrictions
	– dry-cleaning in the solvents listed in the previous paragraph – strict limitations on the addition of water and/or mechanical action and/or temperature during cleaning and/or drying – no self-service cleaning allowed
	– dry-cleaning in trifluorotrichloroethane, with spirit (distillation temperature between 150 °C and 210 °C, flash point 38 °C to 60 °C) – normal cleaning procedures without restrictions
	– dry-cleaning in the solvents listed in the previous paragraph – strict limitations on the addition of water and/or mechanical action and/or temperature during cleaning and/or drying – no self-service cleaning allowed
	– do not dry-clean – no stain removal with solvents

Laundry Sorting. In Europe, all laundry is customarily sorted on the basis of the care symbols described above. The situation in the USA is rather different, primarily because of the use of different washing conditions (cf. Table 18). In particular, average wash temperatures in North America are significantly lower than in Europe, partly due to the absence of heating units in North American washing machines. Temperature recommendations applicable under these conditions are outlined in Table 57. Sorting of laundry in North America is usually limited to that required for producing entire loads subject to a common wash temperature, degree of agitation, and spin speed, as well as to the same laundry aid treatment (Table 58).

Table 57. Wash water temperatures in the USA

Water temperatures	Use
Hot, 130 °F (54 °C) or above	white and colorfast pastels
	heavy and greasy soils
Warm, 90–110 °F (30–45 °C)	dark, bright, or noncolorfast colors
	moderate to light soils
	knits
Cold, less than 90 °F (< 32 °C)	lightly soiled fabrics
	colors that bleed or fade *

* Heavily bleeding coloreds are to be washed separately from other laundry items.

Table 58. Cloth sorting in the USA

Color	Amount of soil	Fabric and construction
White	heavy	permanent-press and synthetics
Colorfast	normal	towels, jeans, and denims
		synthetic knits
Noncolorfast	light	delicates

In Japan, laundry is customarily sorted into three categories, defined solely by the degree of soil: light, normal, and heavy.

Fabric Labeling. Current EC guidelines specify that all textile products offered to consumers must be accompanied by a detailed description of their content of different fibers. A "textile product" in this regulation is any item whose weight is made up of $\geq 80\,\%$ textile raw material.

The guidelines enumerate a very large number of categories covering the entire range of animal, vegetable, and synthetic fibers, including the newest man-made materials. In this context, the term "synthetic" is in itself not considered sufficient and definitive; more explicit identification of material category is required (e.g., polyester, polyacrylonitrile, polyamide, polyurethane, etc.).

Fiber content is specified on the basis of a percentage of net weight, e.g.:

70 % cotton
20 % polyester
10 % silk

Constituent textile raw materials whose contribution is less than 10 % may be collected under the single heading "other fibers." Thus, a product comprised of 72 % cotton, 7 % polyester, 7 % polyamide, 7 % viscose, and 7 % acetate could be labeled as follows:

72 % cotton
28 % other fibers.

13. Washing Machines and Wash Programs (Cycles)

In contrast to the situation in the USA, the beginning of extensive mechanization of the washing process in Europe was delayed until the late 1950s. A major factor in its ultimate arrival was the development of automatic washers operating on regular home electric current, particularly those whose spin cycle was sufficiently balance-controlled so that the machine would not need to be permanently fastened to the floor.

Automation to some extent has long been present in institutional laundries. This has culminated in systems designed to operate on a production-line basis, resulting in a multifold increase in hourly output per employee and a major reduction in required man power. Nevertheless, only a small fraction of household laundry is washed commercially, primarily because the effort involved in doing laundry at home has been so dramatically reduced by the advent of the household automatic washer.

13.1. Household Washing Machines

13.1.1. Classification

Two basic types of home automatic washers exist: vertical-axis machines and horizontal-axis drum machines. In the Americas and Asia vertical-axis washers of the agitator (Fig. 133 [794]) and the related impeller (also called pulsator) types (Fig. 134 [795]) dominate. They both lack internal heating facilities and, therefore, must be connected to an external source of hot water if a heated wash liquor is desired. By contrast, this type of machine has lost virtually all of its former significance in Europe, where it has been replaced entirely by the horizontal-axis drum-type washer (Fig. 135 [796]).

Agitator Machines. Most American agitator-type washing machines mostly have an enameled metal laundry tub. Inside the tub is an open, perforated vertical axis basket, usually of a size suitable for holding up to 5 kg of laundry.

The laundry tub is filled with 50 to 75 L of water, depending on the wash program chosen and the type and weight of the load (medium or large load). Manufacturers recommend that water and detergent be introduced into the machine first, followed by the laundry, which should always be distributed as evenly as possible. Machines of this type normally have two water connections, one for hot water and one for cold. The desired wash temperature (hot, warm, or cold) is selected by proper setting of the controls, and the selected temperature is achieved by automatic mixing of water from the two input sources. Sodium hypochlorite or oxygen bleach may be added separately by hand during the wash cycle, although quite a few machines are equipped with automatic dispensers for the purpose.

After the desired water level has been reached, the agitator is set to function, and the laundry is jostled for ca. 8–18 min by the rhythmic motion of the agitator (Fig. 133). When the wash cycle is complete, the used wash liquor is pumped off. American machines that are set for the regular cycle then begin a series of spins and spray rinses, whereby fresh cold water is sprayed on the load during spinning to remove residual wash water. Water is again allowed to fill the tub for a brief rinse (ca. 2 min), after which it is once more drained off and a final spin drying occurs.

Impeller (Pulsator) Machines. These fully automatic washing machines are used in Japan, China, and other Asian countries. They use a rotating ribbed disk mostly mounted at the bottom of the tub as their source of mechanical input (Fig. 134). Japanese machines have a capacity of 3 to 8 kg of laundry.

Horizontal-Axis Drum Washing Machines. In automatic drum-type washers, the laundry is placed in a horizontal-axis perforated drum which rotates in a tub in alternating directions (Figs. 135 and 136). For a regular cotton wash, only the lower quarter of the drum is filled with wash liquor (bath ratio ca. 1 : 4), which means that, in contrast to agitator machines and pulsator washers, the laundry is only partly submerged. Individual laundry items are repeatedly lifted by paddles located at the inner wall of the drum, each time falling again and tossed into the wash liquor for renewed soaking and rubbing. The wash liquor is heated internally either by means of electrical heating coils located at the bottom of the tub or by a continuous flow heater. A relatively small number of automatic drum-type washing machines are equipped with a separate hot-water inlet for use in households that have access to an economical external hot-water source. In this case the bath is often tempered initially to 30–40 °C by introduction of cold water, thereby preventing proteinaceous soils and stains from being thermally denatured and set in the fabric. Subsequent heating can then take place if this is required by the particular automatic cycle selected.

Laundry is loaded either from the top through an open lid in the side of the drum (top loader) or through its open front (front loader).

Detergent is introduced through a dispenser. In a front loader, the dispenser is usually a device resembling a drawer located at the front of the machine. The dispenser for a top loader

is located beneath the lid of the machine. Dispensers permit automatic sequences consisting of either one or two wash cycles (i.e., a prewash and a main wash). Additional compartments are also provided for the automatic introduction of laundry aftertreatment aids and, especially in Southern Europe, additional automatic dosage of a chlorine-containing bleach during the rinse cycles.

Fully automatic drum type washers utilize one drum for successively accomplishing three separate consecutive operations: washing, rinsing, and spin drying. The machines are equipped with special mechanical devices that compensate for load imbalances. The trend toward space-saving machines has led to the development of smaller washers and washers fitted for built-in kitchens.

Modified European-type horizontal axis drum washers have been introduced in the 1990s in the USA and Japan for reasons of improved efficiency versus current washers in terms of water and energy conservation. Both markets indicate increasing shares of these front loaders. The market shares are, however, still very low.

13.1.2. Operational Parameters

Four factors must be regulated in the washing operation: chemistry, mechanical input, wash temperature, and time.

The effect of each factor on wash performance varies, depending on the washing techniques employed. Figure 137 illustrates graphically by a Sinner's circle the rough percentage influence of the individual parameters on the overall process.

The inner circle implies that the effectiveness of the four factors is a consequence of the medium that unites them, i.e., water.

Figure 137. Circular laundry chart (Sinner's circle)

In the days when laundry was done in an open vat, the required amount of water was large, the role of mechanical action was very limited, and time was a very important factor. A washing machine provides considerably more mechanical action; thus, the wash time has been shortened.

Wash Liquor Ratio. "Wash liquor ratio" (or bath ratio) means the ratio of dry laundry (in kilograms) to the volume of wash liquor (in liters). The total amount of wash liquor required in the overall process is made up of two portions: that which is absorbed by the laundry (bound wash liquor) and that which remains in excess (free wash liquor).

Various washing processes have different wash liquor requirements. North American agitator-type washing machines typically use some 25 L of water per kilogram of laundry, i.e., a wash liquor ratio of 1 : 25, whereas Asian pulsator machines require a ratio of ca. 1 : 20 to 1 : 15. Modern horizontal axis drum-type automatic washers are characterized by a low 1 : 4 wash liquor ratio with cotton, but rather high values of up to 1 : 15 for easy-care and delicate fabrics.

Wash Liquor Level and Reversing Rhythm. A drum-type washer is programmed to rotate in a reversing fashion, i.e., first in one direction and then in the opposite. The extent of the mechanical action imparted to the laundry can be altered by changing either the rhythm of reversal or the wash liquor level (or both). A low wash liquor level (wash liquor ratio of ca. 1 : 4) and relatively rapid reversal (e.g., a reversing rhythm of 12 s of rotation/4 s of pause) causes a large mechanical effect on the laundry. In contrast, a high wash liquor level (wash liquor ratio 1 : 15) and slower reversal (e.g., reversing rhythm 4 s of rotation/12 s of pause) provides less mechanical action, hence the term "gentle cycle".

Residual Moisture. Residual moisture is defined as the amount of water remaining in the laundry after draining and spinning. Data is reported as a percentage of the mass of air-dried laundry. Separate spin drying with a vertical drum permits relatively high rates of rotation: up to ca. 2800 rpm. Corresponding residual moisture levels for a cotton laundry load are typically ca. 40–50 %. Automatic drum-type machines spin dry the load at rates of 400–1800 rpm and result in residual moisture levels for cotton of 100–45 %, respectively.

Wash Temperature. In Europe clothes are commonly washed over a wide temperature range of 30–90 °C, whereas elsewhere much lower temperatures are used (e.g., in North America up to ca. 55 °C, in Asia and South America only up to 25 °C or, in exceptional cases, 40 °C). The high wash temperatures frequently used in Europe for decades before the 1980s had been based largely on tradition and on the firmly held belief that "only clothes that have been boiled are really clean." Nonetheless, this attitude has been changing as a result of the increasing popularity of colored and permanent-press fabrics, the desire to conserve energy, and the introduction of more effective multifunctional heavy-duty detergents, designed for use at a lower temperature (cf. Section 4.1). Today, the predominant washing temperature in Europe is 40 °C. Lower temperatures have long been the rule in North America and in Japan, a fact partly explained by the hygienic function associated with use of chlorine-containing bleaches. Nevertheless, the majority of the world's population (Asia, Latin America, Africa) usually washes at tap-water temperature, i.e., cold.

Table 59. Predominant machine washing conditions

	Europe	Japan	USA
Machine type	Front loader (drum)*	Top loader (pulsator)**	Top loader (agitator)**
Washing time, min	20–60	5–15	8–18
Amount of water, L	8–15	30–60	75
Bath ratio	4 : 1	10 : 1	25 : 1
Temperature, °C	40–60	5–25	10–40
Water hardness	medium/high	very low	low/medium
Detergent dosage, g/L	5–10	0.5	1–2

* Horizontal-axis type.
** Vertical-axis type.

Washing Times. Customary wash times also differ substantially between Europe on the one hand and North America and Japan on the other. Much of the difference is attributable to differences in washing temperatures: relatively low temperatures and the absence of built-in heating facilities in North America and in Japan, as compared to Europe, where a typical washer can heat water to 90 °C. The heating process also consumes a great deal of time. Nearly 40 min are required to raise the temperature of the wash liquor in a drum-type machine to a preset value of 90 °C, not counting the time occupied by a prewash. A wash cycle that includes a prewash entails draining about half of the first wash liquor after it has reached a temperature of about 40 °C at the end of the prewash cycle, which adds ca. 15 min to the process.

The cycles provided for most drum-type automatic washers use the temperature as their time controlling variable. Thus, a high wash temperature dictates a long wash cycle whereas a low temperature requires less time. Meanwhile it has become common for manufacturers to install optional "energy-saving cycles," where a lower wash temperature is compensated for by increasing the wash time. The resulting increase in time and mechanical input accomplishes essentially the same end as a high-temperature wash; the corresponding Sinner's circle reveals that a temperature deficit has been balanced by a gain in time and mechanical action.

Washing machines in the Americas and Asia operate considerably more rapidly. They normally require only 8–18 min for the wash cycle, followed by one or two brief rinse cycles. A comparison of machine washing conditions in Europe, Japan, and the USA is given in Table 59 [797].

13.1.3. Wash Programs

Since laundry habits and washing machines vary considerably in different parts of the world, discussion of washing programs under separate headings reflects the three major traditions: those found in Japan, North America, and Europe.

13.1.3.1. Japanese Washing Machines and Washing Conditions

The washing machines found in Japanese households are of the automatic vertical axis impeller/pulsator type. A declining 25 % of the machines were still semiautomatic twin-tub type washers in 1998. They feature a single housing that contains one separate tub each for washing and spin drying, with the impeller/pulsator located in the former. A characteristic of most Japanese washing machines is the absence of a provision for temperature control, since the process is predominantly conducted at tap water temperature.

The most important variables with a Japanese washing machine are the water level, the weight of the wash load, and the extent of mechanical action. Washing time is adjusted to match the degree of soil of the laundry (ca. 5–15 min). Table 60 depicts program selections of a typical Japanese washer.

Table 60. Program selections of a typical Japanese washing machine

Program		Application
Wash Selector	Automatic program	
	Normal	For normally soiled clothes
	Gentle	For lightly soiled clothes
	Heavy	For heavily soiled clothes
	Hand Wash	For delicate fabrics with hand wash/dry mark
	Dry Cleaning	
	Blanket	For blankets, etc.
	Optional program	
	Wash	– To set preferred program (only wash, wash & rinse, only spin, only drain, etc.) – To set automatic/original wash program.
	Rinse	
	Spin/Dry	
Wash Timer		To set washing time
Water Selector	Level	To set water level. If not selected, washer adjust the level automatically
	Bathtub Water	To recycle used wash water for washing/rinsing. (Tap water is supplied to the last rinse.)
Optional Selectors*	Dosage Selector	For automatic detergent dispensing
	Basket Wash	To remove soap scum from basket using chlorine bleach. (Scum may cause malodor on clothes.)
	Spin Selector	To select spin level, depending on type of garment

* Depending on manufacturer of the washer.

13.1.3.2. North American Washing Machines and Washing Conditions

Although horizontal-axis drum-type machines have gained importance in the U.S. [798] and Canadian markets in the late 1990s, the automatic agitator washing machine still is by far the most common in North American households. Such machines perform a full set of laundry operations in the usual sequence, i.e., wash, rinse, and spin dry. North American machines resemble their Asian counterparts in that they lack heating coils. Therefore, they are designed for connection to domestic supply of both hot and cold water. Three wash temperatures are generally used: hot (55 °C/130 °F), warm (30 to 45 °C/90 to 110 °F), and cold (10 to 25 °C/50 to 80 °F). Rinse temperatures can also be selected, usually from among the two alternatives, warm and cold. One further variable is the water level, which is adjusted according to the quantity of laundry, e.g., medium and large load, and type of laundry to be washed. The mechanical input is also adjustable within limits by introducing changes in the agitator speed and the wash time. The following set of washing programs is typical (cf. Tables 18 and 61):

Regular (heavy-duty wash)
Permanent press
Knit/gentle
Woolens
Soak
Prewash

13.1.3.3. European Washing Machines and Washing Conditions

Horizontal-axis drum-type washing machines in which the water can be heated to up to 90 °C dominate the household market in Europe. To meet the demands posed by current laundry, such machines are provided with a wide variety of wash cycles. In choosing the appropriate cycle for a given load of laundry, the first decision is whether or not a prewash is desired. Options in later stages are supported by the presence of a special third compartment in the detergent dispenser, which permits addition of aftertreatment aids to the final rinse. Machines built for the Southern European market commonly offer a fourth compartment, which allows addition of chlorine bleach to the second rinse.

Selection of the proper cycle is accomplished in one of several ways. Some machines are equipped with one control knob for establishing the program and a separate infinitely variable temperature regulation control. Alternatively, both functions can be combined in one knob while other models offer a set of pushbutton controls. Separate temperature control provides the greatest degree of flexibility.

Management of any wash cycle requires a more or less complicated switching system. Very few machines (mostly those in the lowest price category) continue to be equipped with time-based switching, an approach in which each operation is allowed to continue for a precise and

Table 61. Typical wash programs in North America

Wash program	Fabric	Degree of soiling	Wash time, min	Water temperature	
				Wash	Rinse
Regular heavy	cotton, linen	heavy	12–18	warm or hot	cold
		moderate	10–12	warm	cold
		light	8–10	cold or warm	cold
Knits/gentle	synthetic	moderate	10–12	warm	cold
	delicate	light	8–10	warm	cold
Permanent press	Permanent press cotton, cotton/synthetic fiber blends	heavy	12	warm or hot	cold
		light to moderate	8–12	warm	cold
Woolens	wool	light	4		
Soak	colorfast	heavy	30	cold or warm	none
		stained	30	cold or warm	none
Prewash	colorfast	heavy	6	cold or warm	none
		stained	6	cold or warm	none

Table 62. Typical wash programs for a European drum-type automatic washer

Designation of program	Application	Prewash temperature, °C	Main wash temperature, °C	Cycle		Water level		Number of rinse cycles	Final rinse water retained in drum	Spin drying	
				Regular	Gentle	Low (12–15 L)	High (20 L)			Spin before removal	Regular
Normal ("boiling") cycle, 90°C	whites and fast coloreds (cotton, linen, and their blends)	40	85–90	+		+		3–4			+
Colored fabrics, 60 °C	nonfast colors (cotton, linen, and their blends)	40	55–60	+		+		3			+
White easy-care, 40 or 60 °C	white synthetics (including polyamides, polyesters, and their blends with cotton)	40	40 or 55–60		+	+		3	+	+	
Colored easy-care or delicate washables, 30 °C	colored synthetics, e.g., polyamides and polyesters; polyacrylonitrile, polyacrylonitrile/wool, rayon, acetate, and cupro	30	30		+	+	+	3	+		+
Wool, silk, 30 °C	washable woolens		30/40		+	+	+	2–3	+	+	+
Fabric softener	normal and colored fabrics			+		+					+

predetermined length of time. The principal disadvantage of such a system is that temperature cannot be properly established without taking into account the temperature and volume of the water being introduced and the ambient temperature, all of which can vary.

Modern washing machines are mostly equipped with integrated electronic circuitry based on microprocessors, which may be regarded as microcomputers. These circuits take full functional control of the machine. So-called fully electronic washing machines of this type lack any complex mechanical switching formerly typical of automatic washers.

Modern washers frequently also have so-called fuzzy logic control governing partial processes of the washing program. Fuzzy logics are able to automatically provide, for example, variable speed of reversion of the drum depending on the amount of foam during the wash cycle

[799], provide an additional rinse cycle depending on the quantity of residual foam after the regular final rinse, control the quantity of water intake and washing time depending on weight and type of wash load, etc. Fuzzy logic provides for increased fabric care and water and energy conservation. European washing machines have been reviewed [800].

Today, most garments sold in Europe have uniform labels specifying the use of one of four wash temperatures: 30 °C, 40 °C, 60 °C, and 95 °C (see Table 56). Table 62 gives examples of the wash cycles commonly provided to meet these needs (cf. also Table 18). Similar care labels are found in USA and Japan.

13.1.4. Energy and Water Consumption

Mechanization of the washing process has relieved much of the burden formerly resting on the person doing the wash. At the same time, however, steady increases in energy and water supply costs have made the use of a household drum-type washing machine increasingly expensive. In particular, the cost increases as the selected wash temperature is increased (Table 63), due to the fact that washers are usually poorly heat insulated.

Table 63. Typical energy consumption for various wash programs with a European drum-type automatic washer

Program	Energy consumption, kWh
90 °C Boiling wash program	1.8
60 °C Colored fabrics	1.2
60 °C Synthetics	1.2
40 °C Synthetics	0.6
30 °C Woolens	0.3

It is not surprising that efforts to reduce the costs have begun with the 90 °C cycles, since these hold the greatest potential for energy savings (e.g., by lowering the water temperature from 90 °C to 60 °C). Some washers have herefore incorporated an optional energy conservation program. Such cycles are usually designed to function at 60 °C. Examples of typical energy conservation measures are shown in Table 64. (For information on the related trend in the USA toward washing at lower temperatures, see Fig. 95.)

With respect to conserving water and energy, European washers have made considerable progress during the 1980s and 1990s. This has been made possible through automatic control of the amount of water intake depending on the quantity of the wash load, by omitting the former intermediate cool-down rinse at the end of a hot or warm wash cycle, by considerably increasing the number of revolutions per minute for spinning, applying spray-spinning and, last but not least, by reducing the number of rinse cycles. To encourage consumers to use washing machines that operate with lower consumption of electric power and water all new washing machines manufactured in Europe since 1996 have to display the Energy Label (Fig. 138) as per Official Directive of the European Union. The label indicates the efficiency of the appliance in terms of energy and water consumption, washing performance, capacity, etc. [220].

13.1.5. Construction Materials Used in Washing Machines

Materials used in the construction of washing machines must exhibit a high degree of resistance to various mechanical, heat, and chemical influences. The following materials are particularly well-suited to the purpose:

Stainless Steel. The vast majority of drums are made of stainless steel. Chromium steel continues to be widely used for the construction of tubs, heating coils, and thermostat sensors. Wash tubs have been increasingly constructed from plastic in the 1990s.

Sheet Steel. Casings and lids are made from sheet steel with a protective surface (e.g., enamel paint, baked enamel, galvanization). Baked enamel provides the most permanent form of protection.

Plastics. Certain components can be made from alkali-resistant plastics, usually polypropylene. Typical applications include detergent dispensers, lint filters, paddles, operating controls, mechanical parts, and various small components. Glass fiber reinforced polypropylene has also been employed for tub construction in drum-type machines..

Table 64. Examples of energy conservation programs for European automatic washers

Modification of program	Wash load, kg	Savings in comparison to usual 90 °C-programs, %	
		Electricity	Water
No prewash cycle	4	10	11
Reduction of the washing temperature from 90 °C to 60 °C	4	30	–

Figure 138. European Union energy label

Rubber. Molded rubber is the material of choice for components that require a high degree of elasticity. This applies particularly to gaskets, such as those around the door, as well as to various hoses, hose connectors, and shaft seals. Synthetic rubber is used exclusively for such purposes. A drawback of rubber is its tendency to deteriorate with age. Deterioration is accelerated by exposure to grease, by which the rubber gradually acquires a soft and greasy character.

13.1.6. The Market for Washing Machines

The majority of the world population cleans laundry by hand, washing either in bowls, tubs, sinks, or in river waters. Washing machines dominate only in industrialized global regions.

The percentage of households equipped with washing machines varies considerably among the countries of the EU. Percentages for 1998 are as follows [801]:

Austria	88
France	91
Germany	95
Great Britain	93
Italy	99
Sweden	63
The Netherlands	95
Europe, average	89

In 1998, 3.36×10^6 automatic washers were produced in Germany alone. Total European production was more than 16×10^6 units with a total consumption number of some 11×10^6 in 1998 [801]. A report and analysis on washing machines in Europe has been published. It contains detailed statistical figures for all countries of the European Union [802].

Worldwide, the USA represents the largest single washing machine market. Nevertheless, market penetration in the USA is lower than that in Europe and Japan; 80 % of American households owned a washing machine in 1998 [803]. In the same year, the USA manufactured some 7.0×10^6 washers [803].

More than 99 % of the households in Japan are equipped with a washing machine. The Japanese manufactured 4.4×10^6 units in 1999. Of these, 3.8×10^6 were fully automatic, whereas 0.6×10^6 units were of the twin-tub type.

Market penetration of washing machines in Brazil was 28 % of all households in 2000, in China it was 10 %, and in India 7 % [803].

13.2. Laundry Dryers

Laundry dryers represent a further stage in the development of laundry technology. Dryers are machines that utilize an influx of heat to cause evaporation of the moisture remaining in spin-dried laundry. Electricity is normally used to supply the heat, although some of the dryers in the USA and Europe are heated by gas. Several basic types of dryers exist, including those based on circulation of heated air, heat transfer from metal surfaces, and radiant heating. Most are drum-type machines, so-called tumblers. They can be categorized by the way they dispose of the resulting steam:

Air-Vented Dryers. Dryers in this category function on the same principle as a fan. Ambient air is drawn in by suction, passed through a heated zone, and then introduced into the laundry drum. As the air becomes enriched in moisture, it is vented through a lint filter either directly to the room or out of the building through an exhaust hose or duct.

Condenser Dryers. In these dryers the air needed for drying is drawn from the ambience and passed over a heating device before encountering the laundry. Moist air leaving the tumbler drum is cooled by an additional supply of incoming ambient air. This cooling takes place in the presence of a drip screen, which collects precipitated drops of water. Water from the drip screen collects in a condensate vessel which has to be emptied after each drying cycle. The working principle is depicted in Fig. 139 [796]. The most recent developments comprise condenser dryers that use heat generated by a heat pump [804].

Figure 139. Condenser dryer
a) Ventilator; b) Heater; c) Drying air; d) Tumbler drum; e) Moist air exit; f) Heat echanger; g) Condensing water

Combination Washer–Dryers. The European washer–dryer is a further development of the drum-type washing machine. It is comprised of a washer combined with a water-cooled condensation dryer, and the same drum is used for washing, spinning, and drying. A drawback of these machines is the fact that the small size of the washing drum requires a full load of laundry to be divided into two batches before it can be dried. The heat necessary for drying is supplied either by radiation or by heated air. The market share of these combines in Europe has remained low. In Germany it was only some 4 % in 1999.

Market for Laundry Dryers. The market penetration for laundry dryers in the EU was 27 % on average in 1998 [801]. Percentages for individual countries vary considerably:

Austria	12
France	28
Germany	31
Great Britain	42
Italy	2
The Netherlands	44
Sweden	30

Figure 140. Four common designs for commercial washing machines
A) Open machine; internal drum diameter up to 900 mm; inner drum lacking subdivisions; B) Pullmann type machine; internal drum diameter 900–1400 mm; inner drum divided into two equivalent compartments by means of an axial partition; C) Y-type machine; internal drum diameter 1400–1700 mm; inner drum divided into three compartments by three axial partitions joined along the axis; D) Star-pattern machine, internal drum diameter > 1700 mm; inner drum divided into four compartments by four axial partitions joined along the axis

Major manufacturing countries are Great Britain (1.2×10^6 units in 1998), Germany (0.9×10^6), France (0.5×10^6) and Italy (0.3×10^6). The majority (65 %) of the dryers in Europe are air-vented dryers and the remainder (35 %) represent dryers that use condensation technology.

The situation in the USA is quite different from that in Europe. In the USA, 74 % of all households are equipped with dryers, of which some 27 % are gas-heated, the remaining 73 % being electrically heated units. U.S. production of household dryers amounted to 5.2×10^6 units in 1998 of which 23 % were gas-heated dryers [803].

In 1999, some 20 % of the Japanese households operated a laundry dryer. Approximately 45 % of the dryers have a capacity of more than 5 kg of laundry. The largest part of the remaining 55 % consists of units that have a capacity of 4–4.5 kg.

13.3. Washing Machines for Institutional Use

Washing machines designed for use by commercial laundries are generally designed to keep operating costs as low as possible. As a result, the more labor-intensive batch laundry systems are being increasingly replaced by more efficient continuous devices. In contrast to European households, where laundry water is heated electrically, commercial laundries worldwide usually employ high-pressure steam as their source of heat. Heat from the steam is led into the wash liquor either directly or indirectly, resulting in more rapid heating and shorter wash times.

13.3.1. Batch-Type Machines

There are many situations even today in which batch-type commercial washing machines are indispensable. This is particularly true where a frequent need exists to process numerous small batches of different kinds of laundry. Batch-type machines require a substantial amount of manual supervision; thus, their commercial use is expensive.

Conventional Drum-Type Devices. Such devices are basically scaled-up versions of household washing machines. Commercial front loaders often allow the processing of up to 400 kg of laundry, with special designs allowing even higher amounts. Reversal and rotation rates commonly produce *g*-factors during washing of 0.7–0.9. During spin extraction 400 *g* and higher rates are usual. The large drums require that the effect of mechanical action resulting from great fall heights and excessive weight be moderated and that loading and removing the laundry be simplified. These targets are generally accomplished by introducing into the drum a set of partitions that divide the drum into compartments. Three partitioning schemes (the Pullmann, Y, and star-pattern systems) are illustrated in Figure 140.

Machines of this type are nowadays controlled by microprocessors. Final drying is also performed in large commercial-type equipment.

Wash Extractors. Machines in this category, with a capacity of up to 360 kg, are capable of not only the wash step, but also a spin drying and "fluffing" of the laundered items. Spinning occurs after each wash and rinse operation, an expedient that has the effect of minimizing the number of required rinses. This in turn conserves water and reduces overall wash time to ca. 40 min (Fig. 141). Wash extractors are used in all parts of the world. The machine types, however, vary from manufacturer to manufacturer.

Figure 141. Schematic diagram of a wash extractor

13.3.2. Continuous Batch Washers

The development of the continuous batch washer is a consequence of the demand for a laundry system requiring even less manual intervention. Such machines operate uninterrupted and are best suited to institutions faced with large amounts of relatively uniform laundry. Soiled laundry is loaded onto either a conveyor belt or a suspended conveyor system. As it progresses through the machine, the laundry is exposed to a series of zones designed to accomplish the equivalent of wetting, prewashing, main washing, and rinsing. Most of the zones operate on the countercurrent principle: all water encountered by the laundry flows continuously and in a direction opposite to the motion of the laundry. Each zone leads directly into the next, resulting in significant savings of energy, water, and detergent. Typical water consumption for hospital linen is 8–12 L/kg, sometimes even less.

Following the actual washing process, the laundry is directly loaded into an extraction press or a spin extraction to remove the water. The damp goods are then passed to steam or gas heated batch dryers. The entire process occurs without manual intervention. Continuous batch washers are found all around the globe. But especially in Europe high amounts of goods are treated in this type of machines. Figure 142 illustrates the design of a typical continuous batch washer, in this case one of the Senking type [805].

1. Introduction

The term dextran [*9004-54-0*] refers to those polysaccharides which are composed primarily of $1 \rightarrow 6$ linked α-D-glucopyranose units. Many dextrans contain branches attached to C-2, C-3, or C-4. Others may also contain $1 \rightarrow 3$ linkages in the main chain.

The formation of slimes and jellies during the processing of wines and in sugar refining has long been an undesirable complication. In the middle of the 19th century, reports by PASTEUR [1] and VAN TIEGHEM [2] implicated a bacterial mechanism. The name dextran appears to have been assigned ca. 1870 by SCHEIBLER [3], who also established that dextran was a polymer of glucose. Further references to the early history of dextran are available [4].

Dextrans are synthesized from sucrose by a large number of organisms. JEANES and coworkers have characterized over 96 strains of dextran-producing bacteria [5]. These bacteria are confined to the family Lactobacillaceae and in particular to the genera *Lactobacillus*, *Leuconostoc*, and *Streptococcus*. Several members of the Streptococcus group are implicated in the development of cariogenic plaque on tooth surfaces [6], [7].

Leuconostoc and *Lactobacillus* dextrans are also undesirable contaminants in the sugar refining industry, in which they adversely affect the filterability and crystallization of sucrose [8].

Only the slightly branched dextran from *Leuconostoc mesenteroides B-512 (F)* is of commercial interest. Most of the chemical, physicochemical, and biological reports have therefore focused on this dextran. Unless otherwise stated, the discussions in this article are concerned only with B-512 (F). Figure 1 shows its structure.

2. Structure, Chemical, and Physicochemical Properties

2.1. Structure

The dextran elaborated by *Leuconostoc mesenteroides NRRL B-512 (F)* consists of an $\alpha\,(1 \rightarrow 6)$-linked glucan with side chains attached to the 3-positions of the backbone glucose units. From periodate and methylation analyses, the degree of branching is estimated to be 5 %. Upon hydrolysis, the degree of branching is found to decrease slightly with decreasing molecular mass.

The ^{1}H- and ^{13}C-NMR spectra afford compelling evidence for the main structural features of dextran [9]. The degree of branching of clinical dextrans as determined by ^{13}C-NMR is 4.0 – 6.0 %.

Many details of the fine structure are unresolved, in particular the length and distribution of the side chains. LARM and colleagues concluded that 40 % of the side chains are one unit long, 45 % are two units long, and the remaining 15 % are still longer [10]. The preponderance of single unit branches in several other dextrans, *Leuconostoc mesenteroides B-1375, B-1415*, and *B-1416*, has been established

Figure 1. Structure of a fragment of the dextran B-512 (F) chain

[11]. The availability of dextranases with well characterized properties has permitted WALKER and colleagues to corroborate these results [12]. The presence of a small proportion of longer branches (up to 50 units) is implicit in the studies of the viscosity of dextran [13]. COVACEVICH and RICHARDS [14] concluded that the branches were distributed in a relatively regular manner.

2.2. Physicochemical Properties

Dextran B-512 (F) is freely soluble in water, methyl sulfoxide, formamide, ethylene glycol, glycerol, *N*-methylmorpholine-*N*-oxide, and hexamethylphosphoramide. Some dextran fractions may have adopted a certain degree of crystallinity and can only be brought into solution by strong heating.

The molecular mass of hydrolyzed natural dextran NRRL B-512 (F) is 9×10^6 to 500×10^6 [13], [15]. Measurements in a variety of solvents (e.g., 4 M aqueous sodium chloride and 6 M aqueous urea) failed to reveal any evidence of association.

The relationship between the mass-average molecular mass $\bar{M}_\mathrm{w}$ and the intrinsic viscosity is shown in Figure 2 [13], [16]. GRANATH obtained the viscosity dependence of dextran in the clinical range [16]:

$$[\eta] = 2.23 \times 10^{-3} \bar{M}_\mathrm{v}^{0.43} \ \left(\text{for } M_\mathrm{r} < 5 \times 10^5\right)$$

where $[\eta]$ = intrinsic viscosity and $\bar{M}_\mathrm{v}$ = viscosity-average molecular mass.

The colloid osmotic pressure of dextran solutions significantly affects their plasma volume expansion [17].

Figure 2. Log–log plot of intrinsic viscosity $[\eta]$ against mass-average molecular mass $\bar{M}_\mathrm{w}$ for dextran B-512 (a) and for a hypothetical linear dextran (b)

The $\alpha(1\rightarrow6)$ linked polysaccharides represent a class of very flexible and extended polymers. Table 1 shows the relationship between mass-average molecular mass and the radius of gyration. At high molecular masses, the molecules display increased symmetry [13], [16].

Table 1. Molecular dimensions of dextran B-512(F) [16]

Molecular mass $\bar{M}_\mathrm{w}$	Radius of gyration, nm
2×10^6	38
5×10^5	20
1×10^5	9.5
5×10^4	6.8
(Albumin)	3.5

At M_r 2000, the solution properties are best explained by a transition from a coil to a rodlike conformation. Several attempts have been made to crystallize dextran, and CHANZY et al. grew single crystals from a dextran fraction having M_r 19 900 and proposed a ribbon-like conformation [18].

2.3. Reactivity

As with other glucans, the reactivity of the hydroxyl group at position 2 toward alkylating agents is higher than at position 3 or position 4. Studies on the partial methylation of dextran revealed the following relative reactivities: $k_2 : k_3 : k_4 = 16 : 2 : 7$. Migration of the substituents may subject acylations to thermodynamic control. Thus, although partial acetylation of dextran with acetic anhydride – pyridine in formamide as solvent gave $k_2 \gg k_3 = k_4$, the reactivities were virtually identical when the reaction was carried out with acetic anhydride in aqueous alkali [19].

3. Production

3.1. Biosynthesis

The early work of Beijerinck [20] and Hehre [21] showed that dextran was elaborated by an extracellular enzyme designated dextransucrase (sucrose-1,6-α-D-glucan 6-α-glucosyltransferase, E.C. 2.4.1.5).

The dextransucrases from many *Leuconostoc* and *Streptococcal* strains have been isolated and their properties studied. The purified B-512 (F) enzyme, which binds dextran strongly, rapidly loses activity at 4 °C and even at − 15 °C. Its activity decreases by 60 % over 20 d. The enzyme can be stabilized by adding dextran (> 4 mg/mL) [22].

Dextransucrase appears to be a glycoprotein (M_r 64 000) with mannose being the primary sugar. Calcium ions appear to be essential for the activity of the enzyme.

A mechanism for the biosynthesis has been proposed whereby the enzyme serves two functions [23]. It first hydrolyzes the sucrose and binds the glucosyl moiety, and thereafter it builds up the dextran chain by an insertion mechanism (Fig. 3).

The biosynthesis can be terminated by any one of a large number of acceptors, and if so, the dextran chain is released. Examples of acceptors are maltose, isomaltose, and methyl-α-D-glucoside. Dextran itself can also function as an acceptor [24].

The formation of branches is also an acceptor reaction in which a ring hydroxyl group on a dextran molecule is inserted in the growing dextran chain.

Figure 3. Two-site mechanism for the biosynthesis of dextran chains by dextransucrase
G–F represents a sucrose molecule composed of glucose (G) and fructose (F). G–G represents α (1 → 6) linked glucose residues. The binding sites X may not be identical.

3.2. Production of Clinical Dextran

In the West, most major manufacturers of dextran employ a process based on the batchwise culture of *Leuconostoc mesenteroides B-512 (F)* in the presence of sucrose. The viscous culture fluid is precipitated in an alcohol, and the native dextran then is hydrolyzed and fractionated to the desired molecular mass range. In Japan and Eastern European countries, different strains of *Leuconostoc* are used, but the dextrans produced are of similar structure. The preparation of dextran on a laboratory scale has been described in detail [25], and the industrial production of dextran has been reviewed [26–28].

To obtain vigorous growth of the organism, the culture medium must contain various nutrients in addition to sucrose. In practice, these are supplied by addition of either yeast extracts, corn steep liquors, or malt extracts with peptone or tryptone broth. The pH of the medium affects both the production of dextransucrase by the organism and the activity and stability of the enzyme; Figure 4 shows the pH changes. The influence of sucrose concentration on production of dextran has been reviewed [26]. A sucrose concentration of ca. 10 % is satisfactory; at higher concentrations the yield of dextran with $\bar{M}_w > 5000$ decreases. The cultures are maintained at a temperature of ca. 25 °C, at which the fermentation is complete after 24 – 48 h. Prolongation of the cultures for more than 48 h may lead to a decrease in molecular mass of the dextran.

The native dextran that is obtained is then subjected to partial hydrolysis to form products of appropriate molecular size, and fractionation by ethanol or methanol to give clinical fractions.

Extensive studies on the acid hydrolysis and fractionation of native B-512 (F) dextran have been carried out and conditions for maximal yields have been established [29], [30]. Following the partial hydrolysis, the clinical fraction can be precipitated with 39 – 46 % aqueous ethanol under careful temperature control (25 °C). Membrane technology now often replaces ethanol fractionation in purification operations. The product is then redissolved and spray dried.

Figure 4. Changes in sucrose concentration, pH, and dextran concentration during the fermentation of *Leuconostoc mesenteroides*

3.3. Future Trends

Several alternative processes have been devised over the years:

1) Fermentation with cell-free extracts
2) Fermentation in the presence of acceptors
3) Continuous processes
4) Use of immobilized dextransucrase

About 40 years ago, a supplement (1 mg/mL) of low molecular mass dextran was found to yield a product dextran of lower molecular mass [31]. Few producers have adopted this type of process for clinical dextrans. One drawback is that it requires a production facility for low molecular mass dextran.

Promising results have been obtained with immobilized dextransucrase but only on a laboratory scale [32].

4. Quality Specifications

Monographs for quality specifications of dextran 40, 60, and 70 substance have been published in the European Pharmacopoeia and for dextran 40 and 70 in USP. The molecular size is now determined by size exclusion chromatography. Other quality parameters are acidity/alkalinity, nitrogen impurities, residual solvents, heavy metals, sulfated ash, bacterial endotoxins, and microbial contamination.

5. Storage

Dextran is stable indefinitely when stored in the absence of light, excessive heat, and moisture. Sterile solutions of clinical dextrans with pH 4 – 7 have excellent chemical stability (at least 10 years) when stored at 4 – 40 °C.

Clinical dextran solutions tend to form small amounts of flakes if kept in glass bottles and subjected to considerable temperature fluctuations. These flakes have been found to consist of dextran with the same M_r as the substance in solution. They redissolve upon heating.

6. Uses

6.1. Clinical Products

Dextran 70 (M_r ca. 70 000) is marketed in most countries as a 6 % solution in normal saline and, as such, represents the plasma volume expander of choice. It is one of two plasma volume expanders included in the WHO list of essential drugs. Clinical experience supports its use in the treatment of shock or impending shock as a result of hemorrhage, burns, or surgery. Dextran 60 has replaced dextran 70 in some parts of Europe.

Dextran 40 ($\bar{M}_w$ ca. 40 000) was introduced in 1961 following studies of the erythrocyte disaggregating and blood flow improvement properties of lower molecular mass dextrans. It is marketed as a 10 % solution in normal saline or 5 % glucose which provides rapid plasma volume expansion and promotes microcirculatory blood flow. Both products are used extensively to prevent fatal pulmonary complications of surgery, trauma, and shock. A 6 % solution of dextran 70 in a hypertonic saline solution (7.5 % NaCl) has been shown to be exceptionally effective as a plasma volume expander for primary (prehospital) resuscitation in severe trauma and hemorrhagic shock [33].

In 1982, the monovalent hapten dextran 1 (a fraction of $\bar{M}_w$ ca. 1000) was launched as prophylaxis against dextran-induced anaphylactoid

reactions, which, although rare, may cause undesirable complications in the clinic. Dextrans are commonly added to infusion and perfusion solutions, for example, in connection with transplants. A dextran sulfate of $\bar{M}_w$ 7000 and sulfur content of 16 % was tested clinically as an anticoagulant, but at the doses used, it caused toxic symptoms [34]. A dextran sulfate with M_r approx. 8000 with in vitro antiviral properties has been tested in patients with HIV infection. The results were not encouraging [35]. A diethylaminoethyl derivative of dextran ($\bar{M}_w$ ca. 500 000) has been found to be effective in reducing serum cholesterol.

Iron-dextran products prepared from low molecular mass dextrans are used widely for treating anemic piglets and humans.

In 1977, a cross-linked dextran in bead form (Debrisan) was introduced as a wound-cleansing agent for secreting and infected wounds in particular.

6.2. General Uses

Purified dextran fractions are currently used in the cosmetic and photographic industries. A comprehensive bibliography covering dextran literature and patents is available [36]. Dextran fractions find application for partitioning subcellular particles in two-phase polymer systems and as cryoprotective agents.

Sephadex gels, prepared by emulsion polymerization of dextran, have occupied a dominant place among gel filtration media for many years. Sephadex G-25 is used on an industrial scale for desalting operations during the purification of biopolymers of medical importance, e.g., insulin. Many of the ion exchangers derived from Sephadex are also used commercially for separations [37].

Dextran fractions have been used extensively for preparing conjugates with biologically active substances, e.g., drugs, enzymes, and hormones [38]. Conjugation prolongs the lifetime of the active component in vivo, increases its stability, and facilitates the targeting of the active component. Many derivatives of dextran have been described and numerous patents have appeared. However, few have attained significant commercial interest. Dextran sulfate ($\bar{M}_w$ ca. 500 000; sulfur content 18 %) and diethylaminoethyl dextran ($\bar{M}_w$ ca. 500 000) have revealed an astonishing range of biological activities [39].

Several microcarriers based on cross-linked dextran substituted with cationic substituents (e.g., Cytodex) are used commercially for culturing anchorage-dependent animal cells. As such, they have proved invaluable for the production of vaccines, viruses, and interferon.

7. Economic Aspects

Exact figures for the annual world production are not available but the size of magnitude would be somewhat in excess of 500 t.

The major producer of *dextran* is Amersham Pharmacia Biotech (Uppsala, Sweden); other producers are Meito (Japan), Polfa (Poland), Pharmacosmos (Denmark). The major producers of *clinical dextran solutions* are: Abbott (United States), Baxter-Travenol (Unites States and Europe), Polfa (Poland), Infusia (Czech Republic), Otsuka and Green Cross (Japan), B. Braun (Germany) and Pharmalink (Sweden).

8. Toxicology

The infusion of clinical dextran solutions in humans is now approved by the regulatory authorities in most countries. No adverse effects are to be expected, provided the recommended doses are observed. However, a low incidence of dextran-induced anaphylactoid reactions has been reported. The risk of this type of reaction has been virtually eliminated by the preinjection of 20 mL of a 15 % dextran 1 (M_r ca. 1000) solution [40].

Dextran B-512 (F) given orally is degraded by bacteria in the gut and the products produce a rapid increase in blood sugar and liver glycogen. Dextran administered intravenously is degraded in the liver to carbon dioxide and water.

Dextrans are not permitted as food additives in the United States and Western Europe [41], [42], but they are considered safe as components of food packing materials. Dextrans may be used as additives in pharmaceutical and cosmetic formulations provided that the necessary safety documentation is presented.

MM one of three main iso-enzymes of creatine kinase
MTB methylthymol blue
NAD nicotinamide–adenine dinucleotide
NADH reduced NAD

NADP	nicotinamide – adenine dinucleotide phosphate
NADPH	reduced NADP
NAPH	*N*-acetylprocainamide
NCCLS	National Committee for Clinical Laboratory Standards
NI	neutralization test
OCPC	*o*-cresolphthalein
PAP	prostatic acid phosphatase
PEP	phosphoenolpyruvic acid
PEP-C	phosphoenolpyruvate carboxylase
PET	positron emission tomography
P_i	inorganic phosphate
PMA	pre-market approval application
PNB	*p*-nitrobenzenediazonium tetrafluoroborate
PT	prothrombin time
PTT	partial thromboplastin time
RBC	red blood cell
RE	reticuloendothelial
RIA	radioimmunoassay
RID	radioimmunodiffusion
RNA	ribonucleic acid
SFOV	standard field of view
SLFIA	substrate-labeled fluorescent immunoassay
SPB	supplemented peptone broth
SPECT	single photon emission computed tomography
SPS	sodium polyanetholesulfonate
STAT	medical term meaning "immediate"
TEG	thromboelastogram
TRCHII	tanned red cell hemagglutination inhibition immunoassay
TSB	trypic or trypticase soy broth
TSH	thyroid-stimulating hormone

1. Introduction

Diagnostic reagents can be defined broadly as those chemicals used for the in vitro and in vivo testing, identification, or monitoring of a disease. Although their composition depends on the disease being investigated, these reagents can be composed of a wide variety of materials, ranging from solutions of simple inorganic chemicals to freeze-dried powders or suspensions of complex biologic molecules. Diagnostic reagents are manufactured by many companies worldwide and are packaged in numerous forms and devices for either manual or automated use. These reagents are most often employed in the general professional fields of clinical chemistry, clinical biochemistry, and pathology, as well as in other areas such as medical microbiology, serology, radiology, blood banking, and hematology. Their applications extend from medical research to patient care and even to patient self-testing in the home.

This article describes diagnostic reagents and their applications in general clinical chemistry, immunodiagnostics, microbiology, coagulation, and nuclear medicine. Inorganic reagents [1] and organic solvents [2] used routinely in analytical tests, together with older techniques for blood typing and histology [3], are not described, and the reader is referred to the appropriate references (→ Blood). Flow cytometry, thin-film reagent testing devices, two-dimensional electrophoresis, and immunoelectrophoresis are also not included.

1.1. Medical Significance

Because of their effective use in medical devices, diagnostic reagents have both improved the quality of health care and expanded knowledge of disease. Prior to 1963, most diagnostic reagents were either formulated in clinical laboratories where they were used, or purchased directly from a few chemical supply houses and pharmaceutical companies. The reagents were often used in manual semiquantitative assays or in laborious quantitative methods for determining certain enzymes and metabolites. Quantitative tests generally needed to be done one at a time by using simple spectrophotometers. A few test kits were available for measurement of simple analyte concentrations. However, even these tests were semiquantitative and labor intensive.

The advent of laboratory automation began in 1963, when Technicon Corp. first introduced an *automated clinical analyzer,* based on the continuous flow of reagents, which could perform multiple tests on each sample. Other automated systems, both discrete and continuous flow, have since been manufactured and have changed the way all clinical laboratories operate. Over 60 different tests can now be performed on some automated systems. *Manual kits* are also available for most routine clinical tests, and unlike their predecessors, tests can be run conveniently

and accurately on many samples at the same time by using centrifugal analyzers or multichannel spectrophotometers.

1.2. Economic Significance

In the United States alone, ca. $\$200 \times 10^9$ was spent in 1979 for health care, and over 5.7×10^9 laboratory tests were performed [4]. About 10 % of the total health care costs was attributed to testing, and 5 – 15 % of this was for diagnostic reagents. These numbers have increased during the 1980s, although not as rapidly as during the 1970s, and growth should continue because of the introduction of new diagnostic methods and reagents. The market for diagnostic reagents based on new developments in biotechnology, such as monoclonal antibodies and DNA probes, is expected by some investors to top $\$500 \times 10^6$ by 1987 and to grow to $> \$1 \times 10^9$ during the 1990s [5]. Factors slowing the growth rate of the diagnostic testing market include new legislation in the United States aimed at reducing Medicare payments, a decline in the birth rate, shortened hospital stays, increased cost consciousness by patients and physicians, and increased costs of developing new reagents and methods.

1.3. Regulatory Controls

The introduction of new diagnostic reagents is tightly controlled in the United States under the Federal Food, Drug, & Cosmetic Act of 1938, which was amended in 1976 to include medical devices. All medical devices marketed prior to May 28, 1976, were required by law to be classified by the Food and Drug Administration (FDA) into one of three categories [6]:

1) Class I: devices requiring general controls
2) Class II: devices requiring performance standards
3) Class III: devices for which insufficient information exists for developing controls or performance standards to guarantee safety and effectiveness

In order to sell a novel device classified in Class III, a manufacturer must first submit a premarket approval application (PMA) containing sufficient data to establish its safety and effectiveness. In designing new reagents and test kits, manufacturers may also follow a number of voluntary guidelines established by the American Association for Clinical Chemistry (AACC) [7] and the National Committee for Clinical Laboratory Standards (NCCLS) [8].

Another organization that supplies guidelines, as well as control materials for checking performance of laboratory tests, is the College of American Pathologists (CAP) [9]. Many state agencies now require laboratories to use these control materials to remain accredited.

1.4. Classifications of Diagnostic Reagents

In this review, diagnostic reagents have been classified into three broad categories on the basis of their applications. They are as follows: (1) reagents used to perform general clinical chemistry tests, including the quantitation of electrolytes, serum proteins, enzymes, therapeutic drugs, hormones, and tumor markers (Chap. 2), (2) reagents used to identify microorganisms (Chap. 4), and (3) reagents used to diagnose disorders of the coagulation pathways (Chap. 5). The following two additional categories are based on reagent technology: (4) immunodiagnostic reagents, including both isotopic and nonisotopic materials (Chap. 3), and (5) in vivo reagents for nuclear medicine, including imaging and radiopharmaceuticals (Chap. 6), (→ Radiopaque Media).

Traditionally, microbiologic tests, coagulation tests, and radioisotopic tests have been performed in different laboratories from those in which general clinical chemistry methods are used. This segmentation of effort within hospitals is disappearing as more in vitro diagnostic reagents that bridge the various medical disciplines are developed.

2. Reagents for General Clinical Chemistry

2.1. STAT and Routine Testing

In general, all tests performed in clinical laboratories can be further divided into two operational categories, depending on the priority

of patient treatment. The *STAT tests* are those that typically must be performed quickly in an emergency. These tests usually include analyses of electrolytes (sodium, potassium, chloride, and hydrogen carbonate), creatinine, urea, glucose, and creatine kinase. Results from *routine tests* are not needed as quickly. Examples include methods for measuring serum proteins, hormones, most enzymes, and some therapeutic drugs. Because STAT tests have priority, these assays should be less time consuming and less labor intensive than routine methods. Reagents for STAT methods are ideally more stable and easier to use than others, so that the frequency of calibration is reduced and the time to the first result is minimized.

2.2. Quantitation of Electrolytes

Sodium, potassium, hydrogen carbonate, and chloride are the four most commonly measured ions in serum. Usually, all four are measured on a single sample from the patient because of the important relationships among the ions in terms of acid–base and cation–anion balance. *Ion-selective electrodes* are commonly used to determine concentrations of these ions. However, simple spectrophotometric assays are available for chloride and hydrogen carbonate.

Hydrogen Carbonate. All forms of carbon dioxide (dissolved CO_2, HCO_3^-, and CO_3^{2-}) can be converted to the hydrogen carbonate anion with an alkaline buffer. Hydrogen carbonate can then be accurately *measured enzymatically* [10], using phosphoenolpyruvate carboxylase (PEP-C) (E.C. 4.1.1.32) [*9013-08-5*] in the presence of excess phosphoenolpyruvate ion [*138-08-9*] (PEP) toform oxalacetate ion and inorganic phosphate (P_i). The oxalacetate ion thus formed can be reduced to malate ion by malate dehydrogenase (MDH) with the simultaneous oxidation of reduced nicotinamide–adenine dinucleotide (NADH). The change in absorbance at 340 nm caused by the disappearance of NADH is directly proportional to the total amount of hydrogen carbonate in the sample.

Sodium and Potassium. Measurements of sodium and potassium are most readily performed by using *ion-selective electrodes* that have specific ionophores, such as valinomycin, embedded in the membrane layer. Concentrations of sodium and potassium are calculated from the electrode potential, using the Nernst equation [11–13].

Chloride. The chloride ion, like sodium, is primarily found in extracellular fluids. Hypochloremia (i.e., decreased plasma or serum chloride) may be caused by prolonged vomiting, chronic diarrhea, diabetic ketoacidosis, lactic acidosis, adrenal disease, and renal failure. Hyperchloremia may be caused by hyperventilation, large doses of potassium chloride, and dehydration.

Although there are numerous methods for measuring chloride concentration, including the use of ion-selective electrodes, one easy *spectrophotometric assay* is based on the reaction of chloride with excess mercury(II) thiocyanate to form mercury(II) chloride and thiocyanate, which further reacts with iron(III) ions from iron(III) nitrate [14]. The absorbance at 452 nm caused by formation of red iron(III) thiocyanate is directly proportional to the chloride concentration in the sample.

$$2\,Cl^- + Hg(SCN)_2 \longrightarrow HgCl_2 + 2\,SCN^-$$
$$SCN^- + Fe^{3+} \longrightarrow Fe(SCN)^{2+}$$

2.3. General Chemistry Tests

Typical analyses performed in clinical chemistry laboratories include tests for the concentration of albumin, total protein, calcium, bilirubin, cerebrospinal fluid protein, glucose, cholesterol, high-density lipoprotein (HDL), iron, magnesium, phosphorus, triglycerides, uric acid, and urea. All of the methods for measuring these materials are now automated. Reagent kits are also available for performing these tests manually.

Human serum albumin is commonly measured by its reaction with *bromocresol green* [*76-60-8*] to form a colored complex that absorbs light at 600 nm [15]. Methods with greater accuracy have been developed [16], [17], such as using *bromocresol purple* [*115-40-2*] with a low pH buffer; other determinations rely on either *immunoprecipitation* or *electrophoresis*. Overall, agreement is good between these approaches.

Total protein measurements have been traditionally done by using *biuret* [*108-19-0*] [18] or *Lowry* [19] *reagents,* which form soluble blue complexes. Copper(II) sulfate reacts with peptide linkages of proteins in alkaline solution; the resulting complexes, measured at 540 nm, are proportional to the amount of protein in the sample. A commonly accepted reference method for total protein is available [20] as are numerous other methods.

Calcium [*7440-70-2*] **magnesium** [*7439-95-4*]**, and iron** [*7439-89-6*] can be measured by using *organic dyes,* namely *o*-cresolphthalein [*596-27-0*] (OCPC), methylthymol blue [*1945-77-3*] (MTB), and 4,7-diphenyl-1,10-phenanthroline (bathophenanthroline) sulfonate (BPS), respectively. *Calcium* reacts with OCPC to form a purple complex absorbing at 577 nm, the concentration of which is proportional to the calcium level in serum [21]. Magnesium ions interfere and are removed by chelation with 8-quinolinol.

Likewise, *magnesium* ions form a blue complex with MTB [22], and calcium interference can be minimized by adding the barium salt of ethylenebis(oxyethylenenitrilo)tetraacetic acid (EGTA). Both of these methods are easy to perform and can be completed in < 5 min.

Under acidic conditions (pH 4.2), the protein transferrin can be reduced with hydroxylamine. The *iron(II)* that is bound to this protein is released and forms a red complex with BPS, which absorbs at 540 nm [20, p. 680].

Phosphorus [*7723-14-0*] is usually determined by using a method in which a mixture of 4-methylaminophenolsulfate and bisulfite are used to reduce 12-molybdophosphoric acid [23], [24]. The product of this reaction absorbs at 340 nm and is proportional to the level of inorganic phosphorus in the sample.

Bilirubin [*635-65-4*] . The techniques available for measuring bilirubin include *direct absorbance* [25], *reaction with diazonium salts* [26], and *liquid chromatography.* The most commonly employed methods [27], [28] have been modified extensively by instrument manufacturers. Bilirubin reacts with *p*-nitrobenzenediazonium tetrafluoroborate (PNB) to form a red complex that absorbs at 540 nm. Surfactants, such as Tween 20, can be added to obtain measurements of total bilirubin; in the absence of surfactants the absorbance is more indicative of conjugated bilirubin (attached to glucosyl residues).

Cerebrospinal fluid protein (CFP) is often elevated if the brain or spinal cord are diseased. This material is readily measured by adding *trichloroacetic acid* [*76-03-9*] and determining the resulting turbidity of the protein precipitate at 340 nm [20, p. 423]. Methods using sulfosalicylic acid [29] are also available and generally give similar results.

Glucose [*50-99-7*] . Analysis for glucose is perhaps the most frequently performed assay in the clinical laboratory. Analyses are usually based on well-known enzymatic procedures that use either *glucose oxidase* (E.C. 1.1.3.4) [*9001-37-0*] or *hexokinase* (E.C. 2.7.1.1) [*9001-51-8*] [30]. The former approach relies on the production of hydrogen peroxide, which can react with peroxidase and a colorimetric substrate, whereas the latter depends on the coupling of the hexokinase (HK) reaction product with another enzyme, glucose 6-phosphate dehydrogenase (G6PDH) (E.C. 1.1.1.49) [*9001-40-5*]. Thephosphorylation of glucose by HK in the presence of adenosine 5′-triphosphate(ATP) produces glucose 6-phosphate (G6P). As G6P is consumed by excess G6PDH, nicotinamid – adenine dinucleotide phosphate (NADP) is reduced, producing 6-phosphogluconolactone and NADPH, which has an absorbance at 340 nm that is proportional to the initial concentration of glucose.

Cholesterol [*57-88-5*] test methods are similar to those for glucose and are primarily based on *enzymatic procedures* [31], [32]. Cholesterol esterase (CE) (E.C. 3.1.1.13) [*9026-00-0*] catalyzes the hydrolysis of cholesterol esters to produce free cholesterol, which, along with preexisting free cholesterol, is oxidized in a reaction catalyzed by cholesterol oxidase (CO) (E.C. 1.1.3.6) [*9028-76-6*] to form cholest-4-ene-3-one and hydrogen peroxide. In the presence of horseradish peroxidase (HRP) (E.C. 1.11.1.7) [*9003-99-0*], the peroxide is used

to oxidize chromogenic substrates, such as *N,N*-diethylaniline (DEA) and 4-aminoantipyrine (AAP). The absorbance caused by the colored products is directly related to the cholesterol concentration of the sample. Because **high-density lipoproteins** (HDL) contain cholesterol, levels of HDL can also be estimated accurately by first isolating the fraction of serum proteins containing them and then using the cholesterol methods. At pH 5.7, low-density and very low-density lipoproteins are selectively precipitated from serum by adding buffered phosphotungstate. The remaining clear fraction containing HDL can be decanted and assayed directly.

Triglycerides can be quantitated enzymatically in serum by first using lipase (E.C. 3.1.1.3) [*9001-62-1*] to produce glycerol and then coupling this product to glyceroldehydrogenase (E.C. 1.1.1.29) [*9028-37-9*] [33].The latter enzyme simultaneously reduces NAD to NADH, which absorbs at 340 nm.

Uric acid [*69-93-2*] , which absorbs *light* at 293 nm, may be measured by various procedures. However, one convenient method is to follow the loss of 293 nm absorbance as the uric acid is enzymatically converted to allantoin by uricase (E.C. 1.7.3.3) [*9002-12-4*] [20, p. 538]. The rate of change of absorbance is directly proportional to the concentration of uric acid in serum.

Urea [*57-13-6*] (**1**), or blood urea nitrogen (BUN), is important for diagnosing kidney disease and can be determined by coupling two enzymes [34], namely, urease (E.C. 3.5.1.5) [*9002-13-5*] and glutamate dehydrogenase(GLDH) (E.C. 1.4.1.3) [*9029-12-3*]. Urease specifically hydrolyzes urea to form ammonia and carbon dioxide; the ammonia is a substrate for GLDH, which reductively aminates α-ketoglutarate (KG) ion. In the process, NADH is oxidized to NAD with a loss of absorbance at 340 nm.

2.4. Quantitation of Serum Proteins and Enzymes

Specific serum proteins , such as the immunoglobulins IgG, IgM, IgA, IgD, and IgE, are important for immunity to infections (→ Blood). Abnormalities in plasma IgG, IgA, and IgM occur in many diseases; however, the most noted has been *multiple myeloma,* which results from the rapid uncontrolled growth of antibody-producing cells. A malignant plasma cell tumor may produce any one of the five classes of immunoglobulins, but ca. 50 % of the tumor cells produce IgG and 25 % IgA. Another 20 % produce only single polypeptide chains, usually short chains, which can be detected in the urine as Bence–Jones proteins. Rarely do tumors produce IgD or IgE. *Hypo-γ-globulinemias*, or decreases in immunoglobulins, are usually linked either to hereditary deficiencies in infants or to certain infectious diseases in adults.

Immunoglobulins can be measured turbidometrically, using immunoprecipitation techniques. In *turbidometric* approaches, polyclonal antiserum to human IgG or another immunoglobulin class is prepared from another species (usually rabbit or goat) and used as the main reagent. The pH of the reaction mixture is usually maintained at ca. 7; as the sample and main reagent are mixed, aggregates form between antibodies and human immunoglobulin antigens. The degree of aggregation, measured by the turbidity at 340 nm, is related to the concentration of immunoglobulin in the sample. Antisera for these methods must be chosen carefully to avoid cross reaction by immunoglobulins in other classes and to give reproducible standard curves.

Enzymes in serum or plasma are typically measured to determine the status of organ function because circulating concentrations are usually elevated by diseases affecting specific organs. Lipase and amylase are elevated during episodes of acute pancreatitis. Certain isoenzymes, like creatine kinase-MB, are measured to aid in the diagnosis of myocardial infarction, and different isoenzymes of lactic dehydrogenase are elevated in many disorders, including liver disease and myocardial infarction. Acid phosphatase is used as a tumor marker.

The serum enzyme concentrations of *lipase* and *amylase* usually parallel each other and are often analyzed together on the same sample. Like almost all enzyme methods, these are measured by monitoring the rate of enzymatic reaction either spectrophotometrically or turbidometrically after adding the appropriate enzyme substrate. Substrate levels are typically held well above the Michaelis constant (K_m) of the enzyme to minimize errors resulting from variations in the amount of substrate added [35].

Lipase (E.C. 3.1.1.3) [*9001-62-1*] can be measured directly by using a triolein emulsion, which loses turbidity when it is hydrolyzed to glycerides and fatty acids [36]. Amylase (E.C. 2.4.1.1) [*9035-74-9*], on the other hand, is usually measured with maltopentaose (a linear polymerof five glucose units in an α-1,4-linkage) as a substrate in a reaction mixture containing at least one other enzyme, α-glucosidase (GD), which further breaks down the products of the amylase reaction to glucose. Glucose can then be detected spectrophotometrically with the simultaneous addition of three enzymes, GD, hexokinase (HK), and glucose 6-phosphate dehydrogenase (G6PDH), as well as adenosine 5′-triphosphate (ATP) and nicotinamide–adenine dinucleotide (NAD).

$$\text{Maltopentaose} \xrightarrow{\text{Serum amylase}} \text{Maltotriose} + \text{Maltose}$$
$$\text{Maltotriose} + \text{Maltose} \xrightarrow{\text{GD}} 5\ \text{Glucose}$$
$$5\ \text{Glucose} + 5\ \text{ATP} \xrightarrow{\text{HK}} 5\ \text{G6P} + 5\ \text{ADP}$$
$$5\ \text{G6P} + 5\ \text{NAD} \xrightarrow{\text{G6PDH}} 5\ \text{6-Phosphogluconolactone} + 5\ \text{NADH (absorbs at 340 nm)}$$

Creatine kinase (E.C. 2.7.3.2) [*9001-15-4*], (CK) which catalyzes the transfer of phosphate from creatine phosphate to adenosine 5′-diphosphate(ADP), is also determined by using a method that requires complex reagents. As in the case of amylase, both hexokinase and glucose 6-phosphate dehydrogenase are employed; however, ATP becomes the intermediate reactant and an excess of G6P is added together with NAD [37]. To keep the reagents from reacting before they are needed, they are segregated into convenient solutions or packaged in tablet form. In most methods for CK, adenosine monophosphate and 1,5-di(adenosine 5-pentaphosphate) are added to inhibit adenylate kinase, and ethylenediaminetetraacetic acid (EDTA) is added to suppress calcium inhibition of creatine kinase activity. A sulfhydryl reagent, like dithioerythritol, is also needed to activate the kinase.

$$\text{Creatine phosphate} + \text{ADP} \xrightarrow{\text{CK}} \text{Creatine} + \text{ATP}$$
$$\text{Glucose} + \text{ATP} \xrightarrow{\text{HK}} \text{G6P} + \text{ADP}$$
$$\text{G6P} + \text{NAD}^+ \xrightarrow{\text{G6PDH}} \text{6-Phosphogluconolactone} + 5\ \text{NADH (absorbs at 340 nm)}$$

The method used to measure CK can also be applied to *CKMB,* the MB isoenzyme of creatine kinase. However, CKMB must first be isolated from the two other main isoenzymes of CK, i.e., MM and BB. This can be done with small ion – exchange columns containing cationic and anionic resins, e.g., Biorex 70 and DEAE-sephadex. An immunoinhibition method for CKMB, which actually measures both MB and BB, is available; this method does not require a column separation step. A two-site sandwich immunochemical method, in which the mass rather than the activity of the isoenzyme is measured, is also on the market. All of these approaches give clinically acceptable performance.

Lactate dehydrogenase (E.C. 1.1.1.27) [*9001-60-9*] catalyzes the interconversion of lactic and pyruvic acids and, like creatine kinase, has several isoenzymes that are designated from LDH_1 to LDH_5 by their typical electrophoretic patterns. Liver tissue produces a very high proportion of LDH_5, whereas heart tissue produces a high proportion of both LDH_1 and LDH_2. Total levels of lactate dehydrogenase in serum can be measured by following the rate of absorbance change at 340 nm after adding two reagents, L-lactic acid and oxidized NAD [38]. The liver form of the enzyme (LDH_5) can be measured similarly after its separation from other isoenzymes by using DEAE-sephadex [39]. Another substrate, α-ketobutyrate, works well for the LDH_1 isoenzyme, but not for other forms, and can be used together with reduced NADH to measure LDH_1 activity [40]. When measured in this fashion, the enzyme is often referred to as β-hydroxybutyrate dehydrogenase.

Acid phosphatase [*9001-77-8*] also has numerous isoenzymes; however, only prostatic acid phosphatase is clinically significant because its levels are elevated only during carcinoma of the prostate gland. Although newer methods for measuring this isoenzyme are based on radioimmunoassays and immunoenzymo-

metric assays many laboratories still use a total acid phosphatase method for speed and convenience. Total acid phosphatase can be measured under acidic conditions by adding thymolphthalein monophosphate as the substrate and monitoring the rate of hydrolysis at 600 nm [41].

Serum concentrations of *alkaline phosphatase* (E.C. 3.1.3.1) [*9001-78-9*] are usually elevated by either increased osteoblast activity, leading to the formation of new bone, or by liver disease, in which the bile ducts are obstructed. Because specific isoenzymes of alkaline phosphatase are rarely measured, the methods for determining total concentration of enzyme, using 4-nitrophenylphosphate as a chromogenic substrate, are typically straightforward. As this substrate is hydrolyzed by the enzyme at pH 10, absorbance at 405 nm increases [42]. A variety of buffers have been used with this method; the most preferred is 1-aminopropanol, which acts as a phosphate acceptor and prevents inhibition of the enzyme by phosphate.

Aspartate aminotransferase (E.C. 2.6.1.1) [*9000-97-9*], also known as glutamic oxalacetic transaminase (GOT), is found largely in the liver and heart and is responsible for catalyzing the formation of glutamate ion from α-ketoglutarate by transferring an amino group from aspartate ion. Together with other enzymes, such as creatine kinase, lactic dehydrogenase, and alanine aminotransferase, this enzyme can give useful diagnostic information. Myocardial infarction as well as diseases affecting the liver, such as infectious hepatitis, mononucleosis, cirrhosis, and obstruction of the bile duct, may elevate levels of GOT in the serum. The activity of this enzyme can be conveniently determined by coupling one enzyme product, oxalacetate, to MDH. In doing so, the rate of NAD formation, or loss of absorbance at 340 nm, is proportional to the level of GOT [43].

$$\text{L-Aspartate} + \alpha\text{-Ketoglutarate} \xrightarrow{\text{GOT}} \text{L-Glutamate} + \text{Oxalacetate}$$

$$\text{Oxalacetate} + \text{NADH} \xrightarrow{\text{MDH}} \text{Malate} + \text{NAD}$$

(absorbs at 340 nm)

Alanine aminotransferase (E.C. 2.6.1.2) [*9000-86-6*] , which is also called glutamic pyruvic transferase (GPT), and GOT are usually measured together because changes in concentration of the two enzymes frequently parallel each other. However, GPT typically does not become elevated during a myocardial infarction. Like GOT, this enzyme can be coupled to a dehydrogenase (LDH) through the intermediate pyruvate ion [44].

With most serum enzymes that are measured in clinical medicine, increased levels signify the possibility of disease. With *pseudocholinesterase* [*9001-08-5*], inactivity is usually of interest. This enzyme catalyzes the hydrolysis of choline esters in blood, and its activity can be lowered by organophosphorus poisoning, succinyldicholine hypersensitivity, and liver disease. Because the enzyme can hydrolyze butyrylthiocholine to butyric acid and thiocholine, measurements can be done spectrophotometrically by using 2,6-dichlorophenolindophenol, which reacts with thiocholine [45]. As the reaction proceeds, absorbance is lost at 600 nm.

2.5. Therapeutic Drug Monitoring

Since the mid 1960s, the rational use of therapeutic drugs to combat infection and ease suffering from a variety of diseases has increased dramatically [46]. Drugs, such as digoxin, theophylline, phenobarbital, phenytoin, and aminoglycoside antibiotics, lead the list of agents most often monitored and now account for ca. 25 % of all tests ordered from the clinical laboratory (see Table 1). Monitoring allows physicians to adjust doses, to meet the needs of individual patients, to be certain the drugs are being taken and in therapeutic amounts, and to be sure the levels are below those in which adverse reactions are seen. Many drugs have a narrow range between therapeutic and toxic effects and need to be monitored periodically to assure a safety margin. Other drugs are ineffective unless given at the proper dose; they may have a wider range between the therapeutic and toxic levels. Antibiotics, like gentamicin and tobramycin, may severely damage the kidneys if given in excess.

Methods for measuring the concentration of these drugs by radioimmunoassay (RIA), enzyme immunoassay (EIA), fluorescence immunoassay (FIA), and latex agglutination have been commercialized and are displacing the older analytical techniques [47]. For a detailed

discussion of these new techniques and reagents, see Sections 3.3 and 3.4.

Table 1. Drugs commonly measured in clinical chemistry

Major use	Drug	General therapeutic levels, mg/L
Antiarrhythmic	digoxin	0.001 – 0.002
	lidocaine	1.5 – 5.0
	procainamide	4.0 – 10
	N-acetylprocainamide	4.0 – 10
	quinidine	2.0 – 5.0
Antiasthmatic	theophylline	10 – 20
Anticonvulsant	carbamazepine	3.0 – 9.0
	ethosuxide	40 – 100
	phenobarbital	10 – 25
	primidone	5 – 10
	phenytoin	10 – 20
	valproic acid	∼50 – 100
Antibacterial	gentamicin	2 – 10
	tobramycin	4 – 10

2.6. Measurement of Hormones and Tumor Markers

The development of radioimmunoassay (RIA) technology, with high sensitivity and specificity, has led to many methods for measuring hormones and tumor markers that otherwise would have been impractical. The main reason is that these biologic molecules are present in extremely low concentration (ranging from 10^{-16} to 10^{-9} M) and, thus, are beyond the limits of chromatographic techniques.

Originally, RIA techniques were developed for determining high molecular mass peptides, using competitive binding between labeled antigen and unlabeled antigen from the sample with a predetermined concentration of polyclonal antibody. These methods were subsequently commercialized for low mass haptens, such as thyroxine and cortisol, and a newer technique known as the immunoradiometric assay (IRMA) was developed in the late 1970s for measuring the concentration of proteins. Methods based on IRMA technology give much higher selectivity for the specific analyte compared to RIA methods and employ two monoclonal antibodies, one bound to a solid support and the other isotopically labeled, usually with iodine–125. A sandwich immunoenzymometric assay uses the same approach but with an enzyme covalently bonded to the second antibody (for details, see Sections 3.2 and 3.4).

Although a number of *tumor markers* have been claimed in the research literature, only three are ordered frequently by physicians. These are (1) carcinoembryonic antigen (CEA) (2) prostatic acid phosphatase (PAP), and (3) α-fetoprotein (AFP). On the other hand, the number of *hormones* frequently ordered is considerably larger and includes human chorionic gonadotropin (HCG), thyroid-stimulating hormone (TSH), follicle-stimulating hormone (FSH), human growth hormone (HGH), prolactin, luteinizing hormone, insulin, adrenocorticotropic hormone (ACTH), parathyroid hormone, testosterone, progesterone, aldosterone, cortisol, estriol, and thyroxines (T 3 and T 4). The competitive RIA techniques can also be used to measure other low-concentration substances, such as renin, gastrin, cyclic adenosine 3,5-monophosphate (cyclic AMP), and digoxin.

3. Immunodiagnostic Reagents

Sales of reagents used in immunoassays to diagnose disease and to measure therapeutic agents have been growing exponentially since 1965. This accelerating pace can be attributed to advances in medical technology that have led to the widespread use of therapeutic drugs and to the development of new and convenient in vitro tests for measuring substances. Immunodiagnostic reagents are now used in almost all blood banks to screen samples for infectious disease; in most hospitals, clinics, and commercial laboratories to measure therapeutic drugs, hormones, and tumor markers; and in some physician's offices to monitor levels of certain drugs and to test for pregnancy. These reagents are also part of a growing market for home testing, as exemplified by over-the-counter pregnancy tests that rely on visual detection. Increasingly, methods that use these reagents are becoming both more technologically sophisticated and easier to use because of their packaging, use of nonisotopic markers, and better defined characteristics.

3.1. Polyclonal and Monoclonal Antibodies

Historically, most immunoassays have been developed by using heterogeneous mixtures of an-

tibodies obtained from the serum of animals (usually rabbits, goats, sheep, and horses) immunized with the antigen of interest. These polyclonal antibodies are produced by numerous B cells within the host animal and can differ from each other in terms of their relative concentrations, affinities for the antigen, and recognition of antigen binding sites. The polyclonal antibody populations are also different from one animal to another, which leads to problems in preserving assay performance when one lot of antiserum is depleted.

These concerns can be largely circumvented by using monoclonal antibodies, which were first prepared in 1975 [48], (→ Monoclonal Antibodies). Monoclonal antibodies used in diagnostic assays are typically produced by removing cells from the spleens of immunized mice, fusing these cells with a myeloma cell line, and growing the resulting hybridoma cells in culture. The hybridoma cells are usually screened repeatedly to select those cells producing the desired antibody; the selected cells are then injected into the peritoneal cavities of other mice to produce gram quantities of the specific antibody. Because only one cell line is used to produce the desired antibody, the immunodiagnostic reagent has inherently more uniform properties of affinity and antigen recognition than antibody produced from a combination of cell lines. In addition, monoclonal antibody producing cells can be frozen for long-term storage, reducing lot-to-lot variations. Monoclonal antibodies are now being used in vitro for both radioimmunoassays and nonisotopic immunoassays, as well as in vivo for immunoscintigraphy.

3.2. Radioimmunodiagnostic Reagents

Soon after the first radioimmunoassay (RIA) technique was developed in 1959 [49], there was an abundance of publications regarding new RIA methods for measuring hormones, metabolites, tumor markers, drugs, and a variety of other substances found in low concentration. These early methods typically relied on immunoprecipitation techniques and used one polyclonal antibody reagent per test, together with a radioisotope-labeled antigen. Many of these tests are still being performed, but they have been modified to use other separation techniques and monoclonal antibodies. Radioassays that use binding agents other than antibodies have been commercialized, and many methods now use two or more antibodies per test. The worldwide market for radioimmunodiagnostic reagents (using iodine–125, carbon–14, phosphorus–32, and tritium as labels) has grown to $\$ 1 \times 10^9$/a.

3.2.1. Radioimmunoassays

The first RIA methods were based on *competitive binding reactions* between radioisotope-labeled antigens (such as iodine–131-labeled insulin) and sample antigens for antibody binding. Generally, the resulting immune complexes were precipitated, and the amount of label determined in either the liquid or the precipitate. To obtain well-defined precipitates more quickly, this technique was modified, e.g., by adding ammonium sulfate and a second antibody, such as antirabbit immunoglobulin. Techniques were also developed that used charcoal, which quickly adsorbed any unbound low molecular mass antigens but not antigen bound to antibodies [50].

Most radioimmunoassays employ a *solid phase* that has the specific antibody attached through either covalent bonds or adsorption. The solid phase, such as a coated test tube, is exposed to the sample antigen together with a defined amount of labeled antigen. After an incubation period (ranging from minutes to hours), the liquid in the test tube is decanted and counted to determine the amount of unbound radioactivity. These tests are most often performed on batches of samples and are now being automated [51]. In automated systems, both the bound and free fractions can be measured for radioactivity, which gives an additional check on assay performance.

3.2.2. Radioisotopic Dilution Assays

Methods using this technique are similar to radioimmunoassays in design except that the antibodies are replaced with other binding agents, such as intrinsic factor for measuring vitamin B_{12} and milk-binding protein for measuring folate. These binding agents must be purified from biologic tissues and are now commercially available. Many of these tests also require a step in which the analyte is first separated from an

endogenous-binding protein by boiling the sample or by adding a denaturing agent like sodium hydroxide [52].

3.2.3. Immunoradiometric Assays

An immunoradiometric assay (IRMA) differs from a conventional RIA technique in that *two antibodies are employed;* each recognizes a different binding site on the antigen. One antibody (Ab_1) is immobilized on a solid support and the other (Ab_2) is tagged with ^{125}I.

Immobilized Ab_1 + Ag $\longrightarrow$ Immobilized Ab_1–Ag

Immobilized Ab_1–Ag + Ab_2–^{125}I $\longrightarrow$ Immobilized Ab_1–Ag–Ab_2–^{125}I

These assays do not depend on competitive reactions, but instead are performed in multiple steps:

The sample is exposed to the solid phase (immobilized Ab_1), incubated, washed, and then reacted with the second antibody–tag (Ab_2–^{125}I). After another washing step, the amount of radioactivity bound to the support is measured by using a γ-counter and is directly proportional to the concentration of antigen present in the sample.

Methods that use monoclonal antibodies are becoming more popular for measuring proteins with multiple subunits, such as ferritin, CKMB, IgE, TSH, and B-HCG, and are more specific for the antigen than methods that use only one antibody [53].

3.3. Reagents for Nonisotopic Homogeneous Immunoassays

Most therapeutic drugs and substances that are in the nanomolar concentration range or higher can be measured by using nonisotopic homogeneous immunoassays. These techniques have become popular because they give rapid results, use inexpensive reagents, and circumvent the safety concerns regarding disposal of radioisotopes. In addition, they can be readily automated because no separation step is required.

3.3.1. Latex Agglutination

The first practical homogeneous immunoassay was based on latex agglutination [54]. Micrometer-size polystyrene latex particles coated with adsorbed immunoglobulin were used and were quickly agglutinated by the rheumatoid factor. Latex agglutination assays have since been developed with both antibody- and antigen-coated particles and have been used to measure a wide variety of clinically important substances.

Although most of the early latex agglutination tests were semiquantitative, many have now been developed that can be automatically *monitored* by turbidity, nephelometry, lightcattering, and particle-counting detectors. These tests are generally as quantitative as any state-of-the-art homogeneous immunoassays. The analysis has been stabilized by covalently bonding, rather than adsorbing, antigens and antibodies to latex particles coated with reactive shells. Different polymers with high refractive indices have been used to improve the signal, and in addition, particles of defined size have been synthesized [55]. Agglutination rates are faster for particles in the submicrometer size range, which can be important when designing tests for automated analyzers.

Agglutination tests for the concentration of C-reactive protein, fibrin degradation products, human chorionic gonadotropin, and other proteins usually use particles coated with an excess of a specific antibody. To reduce interference from human rheumatoid factors, either the antibody can be first treated with pepsin to remove the rheumatoid factor binding site, or an excess of rabbit γ-globulin can be added during the assay. Antigen-coated particles are typically employed in assays for low molecular mass substances, such as the therapeutic drugs. In the absence of drug, particles agglutinate when a specific antibody is added, while in the presence of drug, the amount and rate of antibody-induced agglutination is decreased. Drugs, or their analogues that react with the antibody, can be either directly bound to the particle surface, attached through protein conjugates, such as bovine serum albumin, or linked through synthetic spacer molecules, such as polyoxyethylene–polyamine. The choice of attachment chem-

istry is often important for optimal performance and reagent stability.

3.3.2. Enzyme-Tagged Immunoassays

Prior to the advent of quantitative agglutination tests, an enzyme-based immunoassay was developed by the Syva Co. which used a simple homogeneous assay protocol which could be followed by laboratory technicians without special training. As a result, this *enzyme-multiplied immunoassay technique* (EMIT) quickly gained acceptance and is now used routinely for measuring the concentration of therapeutic drugs. The test relies on an enzyme, usually glucose 6-phosphate dehydrogenase (E.C. 1.1.1.49) [*9001-40-5*], to which the drug of interest is covalently bonded nearthe active site. This antigen– (or drug–)enzyme conjugate retains activity until bound by an antibody and, thus, can be used as a marker for the amount of antibody not bound by the sample antigen [56]. Rates of antigen–enzyme conjugate activity are conveniently measured at 340 nm by following NADH production and are inversely proportional to the amount of sample antigen present.

Another homogeneous enzyme-based immunoassay that is used routinely has been developed by the Ames Division of Miles Laboratories. This assay, called the *apoenzyme reconstitution immunoassay system* (ARIES), requires that the antigen be covalently attached to the prosthetic group of an enzyme, such as glucose oxidase (E.C. 1.1.3.4) [*9001-37-0*]. For measuring theophylline levels, an analogue of the drugis covalently bonded to flavin–adenine mononucleotide, and the resulting molecule is added to apoglucose oxidase to reconstitute enzymatic activity. Reconstitution of this activity is inhibited by the presence of free antitheophylline antibody, which is affected by the amount of sample theophylline present. Unlike EMIT methods, which have been adapted to many different clinical analyzers, ARIES technology is currently used only on the Ames Seralyzer.

3.3.3. Fluorescence-Based Immunoassays

As an analytical tool, fluorescence detection is generally superior to absorbance when low levels of fluorescent substances are measured. However, this does not mean that fluorescence–based immunoassays are more sensitive than those based on spectrophotometry because the affinity of the antibody for the antigen is generally the limiting parameter in homogeneous immunoassays. Nevertheless, some fluorescence-based immunoassays have been developed, the most notable of which is the Ames *substrate-labeled fluorescent immunoassay* (SLFIA), automated on the Ames/Gilford Optimate analyzer. This technique employs a fluorogenic enzyme substrate, formed by linking a galactose residue to methylumbelliferone and antigen. β-Galactosidase (E.C. 3.2.1.23) [*9031-11-2*] can hydrolyze the substrate to a fluorescent product, but this reaction cannot occur if the substrate is bound by antibody. Thus, the amount of fluorescence is proportional to the concentration of competing antigen present in the sample. Other techniques based on fluorescence quenching and time-resolved fluorescence have also been reported, but have not gained wide acceptance in the clinical field, partly because they require special instrumentation and complicated manual procedures.

3.3.4. Fluorescence Polarization

When a low molecular mass substance (like phenobarbital) is attached to a fluorophore or its derivative, changes can be measured in the polarization of fluorescence when the conjugate binds to an antibody. This occurs because the rotation of a fluorophore bound to a high molecular mass antibody is considerably slower than that of the free fluorophore and results in a more polarized emission of light. Assays based on this approach rely on competition between the substance to be determined (an analyte) and the analyte-fluorophore conjugate for antibody binding and are generally rapid and reliable. Fluorescence polarization can be used to measure most of the current therapeutic drugs; however,

this method is limited in sensitivity by the fluorescence quantum yield of the selected fluorophore and in scope by the mass of the desired analyte to be measured.

3.3.5. Liposome-Based Immunoassays

Liposomes are small bilayer membrane vesicles that can be prepared by suspending a variety of lipids in water. They can be either multilamellar, containing many internal aqueous compartments, or unilamellar, containing only one compartment per vesicle. When prepared in the presence of soluble marker molecules (e.g., enzymes, ions, fluorophores, enzyme substrates, or inhibitors), the markers are entrapped within the bilayer membranes and subsequently are released during an immunoassay.

The most commonly reported *liposome assay design* uses antigens or small haptens covalently bonded to the lipid membrane [57]. This analysis can be done by linking the antigen to phosphatidylethanolamine (this complex is later used to form liposomes), or by preforming the liposomes and attaching the antigen through a bifunctional cross-linking agent. Specific antibodies bind to antigens on the liposome surface, and the vesicles are then lysed by adding a complement (i.e., a lytic protein typically obtained from guinea pig serum). Antigen from the sample competes with the liposome-attached antigen for antibody binding.

Other immunoassay designs use liposomes that are not coated with antigens, but are instead lysed by hapten–cytolysin conjugates, such as digoxin covalently linked to bee venom melittin [58]. These conjugates retain their lytic activity until they are bound by antibody and can thus be used to monitor competition between the conjugate and analyte in the sample. Heterogeneous assays using antibody-coated tubes together with hapten-coated liposomes have also been developed.

Uses. Liposome-based assays offer potentially a higher signal over other immunoassay techniques because many copies of an enzyme or marker can be loaded within the vesicle. Furthermore, these methods can be used with a variety of detection systems, including spectrophotometers, fluorometers, ion-selective electrodes, and nuclear magnetic resonance spectrometers, depending on the nature of the marker employed. To date, liposomes have been used to measure specific antibodies, IgG, hormones, and therapeutic drugs, such as digoxin and theophylline.

The main concerns regarding these reagents are the preparation of stable liposomes that can be used over several months, the cost of a complement, and the selection of antibodies with the ability both to activate a complement and to bind the antigen with high affinity. As with other homogeneous immunoassays, the ultimate sensitivity for analyte is usually limited by the affinity of the antibodies.

3.4. Reagents for Nonisotopic Heterogeneous Immunoassays

Like most radioimmunoassays, these tests *require preattaching of either an antibody or an antigen to a solid support.* The attachment can be through covalent bonds, simple adsorption, or binding of the immunochemical to a secondary binding agent, such as protein A (from *Staphylococcus aureus*) or another antibody. An important difference between radioimmunoassays and nonisotopic assays is that the latter generally employ enzymes instead of radioisotopes as markers. The enzymes can be covalently linked to either antibodies or antigens by using glutaraldehyde, periodate oxidation, or other bifunctional coupling agents, and the choice of coupling conditions depends on the method being developed. Horseradish peroxidase (E.C. 1.11.1.7) [*9003-99-0*], alkaline phosphatase(E.C. 3.1.3.1) [*9001-78-9*], and β-galactosidase (E.C. 3.2.1.23) [*9031-11-2*] are commonly used because of their high substrate turnovernumbers and because the products of these enzymes can be measured either spectrophotometrically or fluorometrically. Some conjugates have also been prepared by using bacterial luciferase, which can be measured with a bioluminescence detector, as the enzyme.

3.4.1. Enzyme-Linked Immunosorbent Assays

These assays, generally referred to as ELISA, have gained wide acceptance since the mid

1970s for measuring high and low concentrations of high and low molecular mass antigens, primarily infectious disease agents, tumor markers, hormones, and other antibodies [59].

In the most basic case, an antibody is first adsorbed from solution onto a polymeric (often polystyrene) support, which can be premolded into a variety of convenient shapes, such as test tubes, small 6.4 mm beads, and microtiter plates (an array of 96 wells in a plastic tray). After the adsorption step, the support is washed with buffer to remove any unbound antibody, and the sample antigen is added. An enzyme-tagged antigen can be included at the same time to set up a competitive binding reaction; however, this reagent is usually added after a few minutes. The incubation time may vary from minutes to hours before the support is washed again with buffer, depending on the concentration of sample antigen. The second wash step is critical for removing any unbound enzyme-tag and is followed by adding the enzyme substrate. The amount of enzyme-tagged antigen detected on the support is, therefore, inversely related to the concentration of sample antigen.

One frequent *research use* of this technique is to screen monoclonal antibodies for further diagnostic and therapeutic applications. In this case, the antigen is usually adsorbed to the inner surface of microtiter plates, and a second antibody (such as rabbit antimouse IgG) is linked to the enzyme. After the support is washed, samples containing antibodies, which can bind to the adsorbed antigen, are added, and the bound antibodies are detected with the second antibody–enzyme conjugate. This technique gives informa-tion about which cell lines are producing monoclonal antibodies of the IgG class, as well as information about the antibody titer and affinity.

3.4.2. Sandwich Immunoassays

Many antigens, such as HCG, TSH, and ferritin, have multiple epitopic sites and can be measured by using the sandwich immunoassay approach, wherein one antibody is attached to a solid support and another is linked to an enzyme marker. The antigen, therefore, becomes sandwiched between the two antibodies, and the amount of bound antibody–enzyme conjugate is directly proportional to the concentration of antigen in the sample. These assays are more sensitive than competitive type methods because an excess of both antibodies can be used to drive the reaction with antigen (overcoming constraints usually imposed by antibody affinity). The strength of signal generated can also be enhanced simply by incubating the conjugate with the substrate for a longer time.

Tests using this approach can be performed in either of three modes, i.e., forward, simultaneous, or reverse, depending on the order of reagent addition. In the *forward mode,* a sample containing antigen is first added to the solid support to which the antibody is bound. An antibody–enzyme conjugate is then added to react with any captured antigen. After the support is thoroughly washed, an enzyme substrate is added. The wash step in this case is necessary to remove all conjugate that is not bound to the sandwiched antigen. In the *simultaneous mode,* the sample and both antibody reagents are added together. In the *reverse mode,* the sample is first incubated with the antibody–enzyme conjugate. The reverse mode often gives a stronger signal than the forward mode because the antibody–enzyme conjugate can react faster with the antigen when it is in solution than when it is bound to a solid support [60]. Supports used in commercial methods include small polystyrene beads, coated tubes, and magnetic particles.

A *modification* of this approach, which uses two monoclonal antibodies, is described as a Tandem immunoassay [53]. Using monoclonals, Hybritech has commercialized tests for TSH, HCG, ferritin, and carcinoembryonic antigen and has reported others for IgE, luteinizing hormone, and α-fetoprotein.

3.4.3. Affinity Column Mediated Immunoassays

Low molecular mass substances, like small haptens, can be measured accurately by using antibody–enzyme conjugates together with short affinity columns or solid supports containing either the hapten or its analogue [61].

The sample is first incubated with specific antibody–enzyme conjugate, and the resulting solution is then applied to an affinity column. Any specific antibody that does not re-

act with sample hapten binds to the hapten on the solid support; the amount of conjugate passing through the column is directly related to the quantity of sample hapten. Enzyme activity can be measured on either the fraction passing through the column or the bound fraction, depending on the amount of nonspecific background signal that can be tolerated and the purity of the conjugate employed. β-Galactosidase is preferred as a marker when the unbound fraction is measured because this enzyme is not normally present in human serum. Other enzymes, however, can be used when the bound conjugate fraction is determined.

3.4.4. Avidin and Biotin

Avidin, a common protein found in egg white, can bind four molecules of biotin [*58-85-5*] (hexahydro-2-oxo-1*H*-thieno[3,4-*d*]imidazole-4-pentanoic acid), with an affinity constant of 10^{15} L/mol. This tight interaction is essentially nonreversible and has been used in the design of heterogeneous immunoassays in which one immunochemical must be linked either to a solid support or to an enzyme. Many investigators report a higher signal when conjugates of avidin and enzyme are employed with biotinylated antibodies [62]; however, theoretically, no enhancement should be more than threefold above the value found with the use of direct antibody–enzyme conjugates. Biotinylated antibodies have also been linked to supports containing bound avidin, which in some circumstances can lead to slightly increased sensitivity. The incremental costs of using avidin and biotin, therefore, become important when a decision is made whether an assay with an enhanced signal or sensitivity should be developed. Bacterial streptavidin is also available and can be substituted for avidin.

4. Microbiologic Reagents

Most microorganisms, as members of the kingdom Protista [63], are single-cell entities that can only be seen individually with the aid of a light or electron microscope. Viruses are obligate intracellular parasites that do not have cell structure; they possess either DNA or RNA, usually surrounded by a protein-containing coat or capsid and can only be visualized directly by electron microscopy.

This chapter reviews selected diagnostic assays as well as reagents used to determine the quantity and identity of bacteria, fungi, protozoa, viruses, chlamydia, and rickettsia. All microorganisms cited have proven roles in human disease and infectious processes. A short section is included describing products that facilitate collection, transport, and detection of microorganisms from specimens, such as human body fluids. Reagents used in standard or typical methods for microbial detection or identification are also described, and in many cases references and commercial sources of reagents are provided.

Most standard practices in diagnostic microbiology require a culture of a suspected pathogen. The isolated pathogen is typically grown in vitro to increase the population to ca. $10^8 - 10^9$ organisms. This increase in number of organisms permits subsequent diagnostic testing. However, technological advances, such as nonradioisotopic methods of labeling antibodies and nucleic acids, have stimulated development of methods for direct microbial identification. In many instances, these newer direct detection procedures do not require in vitro cultivation of the pathogen. Therefore, diagnostic reagents for detection of microorganisms can be divided operationally into (1) growth-dependent and (2) growth-independent methods. *Growth-dependent techniques* include all methods and reagents that enhance or support growth of target organisms. The organisms are detected by macroscopic evaluation, e.g., of turbidity in broth or of colonies on agar-based growth media. *Growth-independent methods* of detection include microscopy, serology, and newer techniques, such as specific antigen and nucleic acid detection.

Genus- or species-specific antigen detection is more feasible today because of the availability of monoclonal antibodies that are capable of recognizing a specific antigenic determinant (i.e., an epitope) of the target organism. Nucleic acid probes are reagents, like monoclonal antibodies, that can be simultaneously used to detect and identify an organism. The degree of specificity achieved with monoclonal antibodies or

nucleic acid probes is a function of the selection process used to identify and purify the reagent. The major reason that direct specimen detection and identification methods and reagents are gaining popularity is that they save money and reduce time from sample collection to identification compared to traditional approaches. Consequently, the economic impact is the driving force to develop new direct diagnostic methods and reagents.

4.1. Collection, Transport, Processing Devices, and Reagents

Diagnostic tests and associated reagents for use in the clinical laboratory to detect and identify bacteria predominantly depend on bacterial growth. Special precautions, such as antisepsis of the sample site, use of selective media, and microscopy to count the specimen, need to be taken to avoid contaminating patient samples taken from normally sterile body sites. In addition, a properly collected specimen is worthless to the clinical laboratory if it arrives in a condition that reduces or eliminates the identifiability of the disease-producing agent. A comprehensive review of specimen collection and transport practices and procedures used at the Mayo Clinic, Rochester, Minnesota, United States, can be found in *Laboratory Procedures in Clinical Microbiology* [64].

Increasing emphasis has been placed on methods of collecting and transporting clinical samples to the testing laboratory. Many new commercial devices that enhance recovery efficiency, stabilize the viable microbial concentration, or process the specimen to enhance recovery have been introduced. For example, septicemia requires a diagnostic test for detection of bacteria or fungi in blood. Currently, this can be accomplished only by isolating or growing the organism from the sample. Typically, blood is aseptically collected in devices containing a suitable anticoagulant, e.g., sodium polyanetholesulfonate (SPS), for transport to the clinical microbiology laboratory.

Blood Collection Devices. The simplest device is a sterile, rubber-stoppered, SPS containing Vacutainer, manufactured by Becton Dickenson. Another blood collection, transport, and processing device is the Du Pont Isolator microbial tube. In addition to containing SPS, the Isolator allows for concentration of microorganisms by centrifugation. The concentrated bacteria or fungi are plated directly onto various agar-based growth media in petri plates, which results in the growth of isolated colonies 18 – 24 h sooner than broth culture methods [65]. Other blood transport devices are blood culture bottles and tubes containing SPS and a liquid growth medium or broth, including soybean-casein digest, e.g., Trypic or Trypticase soy broth (TSB), brain heart infusion (BHI), Brucella, Thiol, thioglycolate, Columbia, and supplemented peptone broth (SPB). United States manufacturers of blood culture media include Difco, BBL, Scott, and Roche.

A new device made by Roche called Septi-Chek has a built-in slide subculturing chamber, which has chocolate, MacConkey, and malt agar surfaces. Microorganisms growing in the broth phase are simultaneously subcultured onto the agar surfaces and form colonies. The antimicrobial removal device (ARD) by Marion Laboratories is a sterile bottle containing ion-exchange resins that remove antibiotics from the patient's blood. Following antibiotic removal, the sample is transferred to a culture system. The ARD is intended for use in those cases in which patients are known to be receiving antimicrobial therapy and septicemia is suspected.

Urine collected for microbiologic analyses, e.g., bacteriuria, requires either prompt analysis (ca. 2 h) or refrigeration because urine is an excellent growth medium, and the concentration of bacteria or fungi in urine is indicative of urinary tract infection. The BD Urine Culture Kit is a new device and approach to urine transport. Patient urine is added to a sterile tube containing glyceroboric acid in sodium formate. These reagents stabilize and maintain the microbial count from the time the sample is collected until it is analyzed.

Although not a collection or transport device, the new Chemstrip LN (Boehringer Mannheim) is a *rapid urine screen for bacteriuria* and is claimed to have a negative predictive value of 97.2 %. The Chemstrip LN is a 2-min dip-strip test specifically for leukocyte esterase and nitrate reductase. Urine culture is indicated only if the urine sample shows a positive Chemstrip LN

test. Other microbial devices and reagents include Meridian ParaPak for recovery or straining of protozoan parasites from feces, Culturette collection systems (Marion Scientific) for swab samples, and Anaerobic Specimen Collector (Becton Dickenson), which is an anaerobic swab collection system for wounds and abscesses.

4.2. Growth-Dependent Microbial Reagents

Growth-dependent methods of microbial diagnosis have, in many cases, been selected from among processes occurring for over 100 years.

The success of culture-based methods for detecting and identifying bacteria, fungi, protozoa, viruses, chlamydia, and rickettsia depends on establishing *optimal environmental and chemical growth conditions.* The growth medium or reagent must possess all necessary nutritional requirements to support microbial multiplication. Bacteria, fungi, and protozoan parasites can be cultivated in vitro by using chemically defined media. Growth of protozoan parasites often seems to be more art than science [66], because complex biologic fluids, e.g., egg yolk, gastric mucin from hog stomach, and serum, must be included to achieve optimal results. Occasionally, *fastidious* bacteria and *mycoplasma* species require additional factors, such as blood, hemoglobin, serum, coenzyme(s), or hematin.

Recommendations and formulations for cultivation of the various categories of microorganisms are found in the following publications: bacteria and fungi [64], [67–72], protozoa [66], [67], viruses [64], [67–70], and chlamydiae/rickettsiae [64], [67], [68], [70]. Manufacturers of prepared media include BBL Microbiology Systems, Difco Laboratories, Fisher Scientific Co., GIBCO, M. A. Bioproducts, Flow Laboratories, K. C. Biologicals, and Scott Laboratories. Linscott's *Directory of Immunochemical and Biological Reagents* (1984 – 1985) lists worldwide suppliers of media and reagents. All manufacturers provide the chemical formulations for commercial media, which also serve as references for media composition.

Viruses and chlamydiae are all obligate, intracellular parasites. These organisms require *host cells* for in vitro cultivation. Host cells are typically primary, secondary, or continuous [63], [69] as well as either fibroblastic or epithelial in origin. In vitro isolation and detection of viruses and chlamydiae require permissive or susceptible host cells. The pathogen must be capable of entering the cells and multiplying. In most cases, clear characteristics of infection are obvious by low-power (40 – 100 ×) phase-contrast microscopy after 1 – 2 d for Herpes simplex or polio virus, or weeks for cytomegalovirus [63], [69].

Cell cultures can be purchased or obtained as gifts from *commercial sources.* In the United States, Flow Laboratories, M. A. Bioproducts, and BBL Microbiology Systems are major suppliers of cell cultures. The American Tissue Culture Collection (ATCC) is another source for cell cultures. Primary cell cultures are routinely prepared in large virology laboratories from rabbits (kidney), guinea pigs (whole embryo), or chickens (whole embryo) [69] or can be purchased as ready-to-use monolayer cultures from commercial sources.

Growth-dependent methods for recovery of viruses and chlamydiae are costly and time consuming. However, in many cases, culture remains the method of choice based on consideration of clinical sensitivity and specificity.

4.3. Immunodiagnostic Reagents in Clinical Microbiology

The *serological determination* of bacterial infection is performed by measuring the quantity of antibody present in patient serum that specifically reacts with a selected antigen preparation. Antigen selection and preparation for use in a diagnostic assay are the most important reagent-related variables. Table 2 lists clinically significant bacteria, fungi, and protozoan parasites whose detection or identification often is performed by using serological methods. Similarly, Table 3 lists serological assays, tests, and reagents used to diagnose viral, rickettsial, and chlamydia infections. The antigenic preparation used for each organism is also listed along with literature references and, in many cases, commercial sources for the specific organism or antigen preparation. Standard serological tests used to identify and type bacteria include precipitation reactions (e.g., ring test,

quantitative precipitation, capsular swelling, gel diffusion methods, and immunoelectrophoretic methods), complement fixation, neutralization tests, cytolytic methods, agglutination assays, flow cytometric analysis, and immune electron microscopy [72], [77].

Table 2. Antigen reagents used in serological assays for selected bacteria, fungi, and protozoan parasites

Microorganism	Antigen reagent and commercial source
Group A β-hemolytic streptococci	streptolysin O; deoxyribonuclease β; hyaluronidase, Difco, GIBCO, Fisher [68], [73]
Streptococcus pneumoniae	capsule polysaccharides; Difco [73]
Neisseria meningitides	capsule polysaccharides; outer membrane proteins; lipopolysaccharides; pili [67], [70], [73]
Neisseria gonorrhoeae	phenol extracts, lipopolysaccharide; pooled cells; soluble fraction from physically disrupted cells; pili [73]
Salmonella typhi	somatic (0 antigens) flagellar antigens, H antigens; Difco
Vibrio cholerae	somatic (0 antigens) heat labile enterotoxin; Y cholerae serotype Ogarva (strain VC12) and serotype Inaba (strain VC13)
Yersinia enterocolitica	0 antigen (lipopolysaccharide)
Yersinia pseudotuberculosis	0 antigen (lipopolysaccharide)
Pasteurella multocids	soluble extract from heated cells [73]
Francisella tularensis	formalin-treated whole cells or commercial preparations; Lederle, Difco, BBL [73]
Haemophilus influenzae Type B	capsule polysaccharide, polyribose phosphate (PRP) [68], [70]
Brucella abortus	surface antigens A and M
Brucella suis	surface antigens A and M
Brucella melitensis	B. aborus strain 1119 used as antigen standard
Bordetella pertussis	whole cell preparation B., pertussis strain 460 [a]
Legionella pneumophila	*L. pneumophila*
Microorganism	Antigen reagent and commercial source
	A antigens serotypes 1 – 4 heat-killed organisms [b]
Pseudomonas pseudomallei	*P. pseudomallei* strains 8202, China 3 and 292 heat-killed, cell-free supernatant [73]
Listeria monocytogenes	*L. monocytogenes* serotype 1 a, NCTC 7973, H.P.R. Seeliger, ATCC 19 111 and serotype 4 b, F 4, J. Donker-Voef [b]
Corynebacterium diphtheriae	*diphtheriae toxoid;* "Schick test" [73]
Cloareisium tetani	tetanus toxoid "Schick test" [73]
Mycobacterium tuberculosis	*M. tuberculosis* strain DT-612 [c]
Treponema pallidum	*T. pallidum* antigens available from a variety of manufacturers [68], [70], [73], [74]
Mycoplasma pneumoniae	*M. pneumoniae*
Mycoplasma lomines	fraction from
Ureaplasma urealyticium	chloroform – methanol extraction *M. homines* and *U. urealyticum* nonlipid fractions
Aspergillus fumigatus	culture filtrate,
Aspergillus flavus	acetone precipitated;
Aspergillus niger	Meridian M.A. Bioproducts
Micropolyspora faeni	Greer Labs
Thermoactinomyces candidus	
Thermoactinomyces virlgaris (actinomycotic hyper-sensitivity pneumonitis)	
Paracoccidioides brasiliensis (paracoccidioidomycosis)	concentrated yeast filtrate antigens; [12]; CDC stock P. brasiliensis B339, B341 & B1183
Skporothrix schenckii	*S. schenckii* reagents not commercially available [73]
Giardia lamblia	[66], [67], [73]
Entamoeba listolytica (amebiasis)	[66], [67], [73]
Trichomonas vaginalis	[66], [67], [73], [75]
Trypanosoma cruzi	[67], [73], [75]
Trypanosoma gambiense (African trypanosomiasis 0)	
Leishmania donovani	
L. tropica	[73]
L. braziliensis (leishmaniasis)	Burroughs Wellcome
Plasmodium falciparum	[73]

Table 2. (Continued)

Microorganism	Antigen reagent and commercial source
P. vivax (malaria)	
Pneumocystic carinii (pneumocystosis)	[73]
Toxoplasma gondii (toxoplasmosis)	[73]
Other miscellaneous parasitic diseases: echinococcosis, schistosomiasis, fascioliasis, trichinosis, filariasis, ascariasis, Chagas' disease	[73]

[c] Mycobacteriology Branch, Center for Disease Control, Atlanta, Ga. 30333, United States

An example of one of the most commonly employed immunoassay test configurations for serodiagnosis uses antigen immobilized on a solid support, e.g., on the walls of a polymer tube, on the surface of polymer spheres, or in the wells of a plastic microtiter plate. Serum samples are added to the solid supports and allowed to react. Unreacted material is washed away and a labeled second antibody is added to all test chambers. As in many immunoassays, a blocking substance, e.g., 1 % bovine serum albumin or ovalbumin, is added to minimize nonspecific binding reactions. Unreacted material is washed away and the amount of specific human antibody bound to immobilized antigen is measured.

This type of immunoassay is designated an *indirect, heterogeneous immunoassay* because two antibody reagents are employed and reagents must be added sequentially and separated by washes to remove unreacted reagents [73], [74], [76]. Direct antigen and nucleic acid detection are discussed in Section 4.4.

4.4. Monoclonal Antibody and Nucleic Acid Assays

Monoclonal antibodies and nucleic acids (DNA probes) are highly sensitive and specific diagnostic reagents. A **monoclonal antibody reagent** consists of one antibody type that recognizes a specific antigen or epitope. Monoclonal antibodies are produced by specialized hybrid cells called *hybridomas,* which are made by fusing antibody–secreting cells with cancer cells. Hybridomas can be frozen for long-term storage, ensuring a uniform source of antibodies.

Monoclonal antibody reagents can be produced continuously in a reproducible fashion and can be highly purified and characterized. However, in spite of the obvious advantages, the ultimate role of monoclonal antibodies in microbial diagnostics remains uncertain. The reason for this uncertainty is that microorganisms are capable of altering their antigenic appearance as a result of genotypic (mutagenic) or phenotypic (environmental) changes. Such changes can prevent the highly specific monoclonal antibody from recognizing a desired target (epitope) and, thus, render the assay useless. One method of circumventing this problem is to choose monoclonal antibody reagents that react with highly conserved microbial antigens.

Regardless of strategy employed to produce a monoclonal antibody, it is highly desirable and advantageous if the selected antibody has both suitable affinity and avidity [72].

This distinction between diagnostic targets subject to genetic or environmental changes (e.g., microorganisms) and those targets that are constant (e.g., drugs and hormones), more than any other differences, accounts for the broader use of monoclonal antibodies in clinical chemistry than in diagnostic microbiology. Continued research on the application of monoclonal antibodies for microbial diagnostics will undoubtedly minimize the importance of these distinctions.

DNA probes are pieces of nucleic acid chosen because they specifically hybridize to a target nucleic acid located within an organism. The DNA probe is generally a *single-stranded nucleic acid* consisting of > 20 bases and is labeled in some way to permit detection. Common *labels* include radioisotopes, enzymes, or chemiluminescent or fluorescent molecules.

Labeled DNA probes can be reacted (i.e., hybridized) directly with a target nucleic acid (complementary and single-stranded) bound to a solid support. An example is filter hybridization in which single-stranded target nucleic acid is bound to a nylon or nitrocellulose membrane

Table 3. Serological assays [a], tests, and reagents used to diagnose viral, rickettsial, and chlamydial infections

Organisms	Tests [b]	Reagent sources and references
Herpes simplex	CF, IFA, NI, RIA, EIA	ATCC, Ortho, Boots-Celltech, Syva, Biotech Research Labs, Wellcome Diagnostics, Gull Labs, Litton Electro-Nucleonics, Dako [70], [72], [76]
Cytomegalovirus (CMV)	latex agglutination, EIA	Hynson, Westcott & Dugging, M. A. Bioproducts, Litton Bionetics, Biotech Research Labs, Wellcome Diagnostics [73], [76]
Varicella-Zoster virus (VZV)	CF, FA against membrane antigen (FAMA)	Flow, M. A. Bioproducts [70], [73]
Epstein-Barr virus (EBV)	elevated Ab levels (IFA) to EBV viral capsid (VCA), EBV membrane antigen, EBV nuclear antigen (EBNA), and EBV early antigens or heterophile antibody test	[68], [69], [73], [74]
Influenza virus Type A	HI, HAD	GIBCO, Flow, M. A. Bioproducts [69], [73], [74]
Influenza virus Type B		
Respiratory syncyteal virus (RSV)	CF, HI, NI, EIA	M. A. Bioproducts, Flow, BBL [63], [69], [70], [73], [74], [76]
Parainfluenza virus (Types 1 – 4)	CF, HI, NI, EIA	M. A. Bioproducts, Flow, BBL [63], [69], [70], [73], [74], [76]
Measles	HI, CF	Flow, M. A. Bioproducts [68], [73], [74]
Mumps	HI	Flow, M. A. Bioproducts [68], [73], [74]
Adenovirus	CF, HI, NI	M. A. Bioproducts, Flow [63], [69], [73], [74]
Rubella	HI, NI, CF, EIA latex agglutination, passive HA	Abbott Labs, Ortho Diagnostics, Flow, M. A. Bioproducts [70], [73]
Togaviridae (Eastern equine) encephalomyelitis, Western equine encephalomyelitis, yellow fever, tick-borne	HI, CF, NI; also EIA, FA, RIA	[69], [73], [74]
Bunyaviridae (Rift Valley fever, Phlebotomus fever, and LaCrosse)	Hi, CF, NI; also EIA, FA, RIA	[69], [73], [74]
Arinaviridae (lymphocytic choriomeningitis, Lassa virus, and Tacaribe, Pichinde, and Flexal viruses)	CF, IFA, FA, NI	[63], [69], [70], [73], [74]
Entero viruses (polio virus and echovirus)	isolation (culture) usually preferred to antigenic variance NI, CF (polio) HI, FA	M. A. Bioproducts [73]
Reovirus (Types 1, 2, & 3)	HI, NI, CF	M. A. Bioproducts [73]
Hepatitis viruses Hepatitis A	detection of Hepatitis A antigen in stool –	[73], [74], [76]

[72], [77], [78]. Labeled, single-stranded nucleic acid is then hybridized to complementary sequences bound to the filter, and unhybridized DNA probe is washed away. The labeled, hybridized DNA is detected and the amount that is bound is compared to positive and negative controls. DNA probe reagents can be *amplified* either biologically through a recombinant vector or synthetically by oligonucleotide syntheses. If desired, nucleic acid probes can be *synthesized* on the basis of known amino acid sequence data. Finally and most importantly, the *chemical basis* of all nucleic acid probe–nucleic acid target hybridization reactions (which defines clinical assay specificity) is complementary base-pairing (hydrogen bond formation) and stabilization of the resulting duplex via hydrophobic interactions between stacked bases.

Table 3. (Continued)

Organisms	Tests [b]	Reagent sources and references
	RIA, EIA, IEM	
Hepatitis B	HBsAg; anti-HBs detection; anti-HBc detection – RIA, EIA, latex agglutination	[73]
Hepatitis non-A, non-B	essentially none available; negative test results for Hep A and Hep B indicate presumptive positive for Hep non-A, non-B	none available
Rotavirus (infectious gastro-enteritis in children)	demonstration of rotavirus in stool using EIA, RIA, IEM or rotavirus-specific antibody in serum – EIA, RIA, CF	Abbott Labs [73]
Chlamydia trachomatis (Trachoma and venereal disease)	CF, FA, IFA	[73], [74], [76]
Rickettsiae (Rocky Mountain spotted fever, Q fever, etc.)	IFA, CF, Weil-Felix	[73]
Human tumor leukemia HTLV-III (cause of human-acquired immunodeficiency syndrome, AIDS)	IA, RIA, (HTLV-III antigens coated onto solid phase)	Abbott Labs, Litton-Bionetics, Electronucleonics, Du Pont

[a] A variety of the serological assays, e.g., neutralization test, hemadsorption, hemadsorption inhibition, and fluorescent antibody (direct and indirect) often require virus-infected cell cultures; such assays are growth-dependent methods; however, newer test methods that employ an antigen-coated solid phase, e.g., latex agglutination, EIA, RIA, do not require cell cultures and are appropriately listed as growth-independent methods and reagents.
[b] Tests: CF = complement fixation; EIA = enzyme immunoassay; HAD = hemadsorption; HI = hemagglutination–inhibition test; IAH = immuneadherence hemagglutination; IEM = immunoelectron microscopy; IFA = indirect immunofluorescent staining; FA = immunofluorescent staining; NI = neutralization test ; RIA = radioimmunoassay.
[c] Biological Reagents Branch, Scientific Resources Division, Bureau of Laboratories, Center for Disease Control, Atlanta, Ga., United States.

The pressure to *reduce health care costs* may influence the choice of technology used for microbial detection and identification. Methods that detect and identify pathogens directly from the patient specimens produce faster results than culture-based methods. Improvement in test turnaround time, i.e., time from sample collection to result, should produce improved administration of chemotherapy. Use of rapid diagnostic methods could also reduce the time of hospitalization for some patients. Consequently, in many cases, traditional culture-based, growth-dependent microbial diagnostic methods will be displaced by nonculture, growth-independent methods. The decision, however, to adopt new direct detection methods must be based on clinical utility and cost effectiveness.

5. Coagulation Diagnostic Reagents

5.1. Introduction to Hemostasis

Hemostasis is the complex mechanism by which blood is maintained in a fluid state within the circulatory system (→ Blood), [79–87]. It involves the intimate interaction of blood vessels, platelets, and soluble plasma proteins. Disorders of any of these components can lead to serious bleeding or clotting problems. Because of the complex nature of the system and the diversity of pathological consequences, many varied tests are required to evaluate the integrity of the hemostatic system.

Blood Vessels. Although some new tests are emerging, diagnosis of disorders of the blood vessels that affect hemostasis is difficult. A physical examination may be necessary for recognition of overt vascular defects. Abnormal bleed-

ing times or tourniquet tests are two nonspecific indicators of vascular disorders. As the molecular mechanism of the interaction of platelets and soluble plasma proteins with the vascular endothelia becomes better understood, more direct clinically significant tests may emerge.

Platelets. Platelets are circulating cells containing proteins and other factors that interact with the vessel wall and with soluble plasma proteins. Pathological disorders of platelets can cause bleeding disorders and may also contribute to problems such as atherosclerosis. Measurement of platelet number and function (bleeding time) are routinely performed and other specialized tests are becoming more widely used.

Plasma Factors: Screening and Specific Tests. The common screening tests for hemostasis *evaluate the overall integrity of the blood coagulation cascade* (→ Blood, Chap. 2.1.). The coagulation cascade is extremely complex, and generalized screening tests are useful to confirm normal function. Certain disorders require more specific diagnostic tests for individual factors or for inhibitors or activators that modulate the factors. The proper dissolution of blood clots through the fibrinolytic pathway is also required for normal hemostasis and several diagnostic tests are available and useful in detecting fibrinolytic disorders.

Anticoagulants. Cardiovascular disorder, often caused or potentiated by the improper regulation of the hemostatic system, is a leading cause of death. Anticoagulants are widely prescribed for *thrombotic episodes.* Proper therapeutic maintenance requires specialized tests that monitor the function of these drugs.

5.2. Screening Tests

Screening tests are widely used to evaluate the overall integrity of the coagulation pathways. In general, they are used for presurgical screening to avoid bleeding complications, for monitoring anticoagulant therapy, and for evaluating bleeding disorders. Screening tests are of limited value in detecting thrombotic disorders.

Prothrombin Time. The prothrombin time (PT) test was developed in 1935 and is *used to determine the status of the extrinsic system* (factors I, II, V, VII, and X). Patient's plasma (0.1 mL) is mixed with 0.1 mL of tissue thromboplastin and 0.1 mL of a calcium chloride solution at 37 °C, and the time to clot formation is measured. Various manufacturers produce the thromboplastin reagent, which contains extracts from animal or human brain or lung tissue (see Table 4). The PT results can be reported directly as the clotting time (along with the clotting time for a control plasma), a ratio (test : control), or a percentage (based on dilution of normal plasma with saline). Control plasma materials are commercially available and can be prepared from a normal plasma pool.

The test procedure is fairly well standardized, and results are generally reproducible within a laboratory. Unfortunately, test results vary between laboratories because each thromboplastin reagent has a different pattern of sensitivity to the various extrinsic coagulation factors. Besides its use for general screening, the PT test is used to monitor oral anticoagulant therapy.

Activated Partial Thromboplastin Time. The activated partial thromboplastin time (APTT) test *measures the integrity of the intrinsic system of coagulation.* It is sensitive to deficiencies in factors I, II, V, VIII, IX, X, XI, and XII. A mixture of 0.1 mL of patient's plasma and 0.1 mL of a phospholipid–surface activator mixture is incubated. Calcium chloride solution (0.1 mL) is added to initiate clotting, and the time required to form the initial fibrin clot is measured. The phospholipid–surface activator mixture is critical to the performance of the APTT test. Different sources of phospholipid (e.g., rabbit or bovine lung tissue or soybean extracts) and different surface activators (e.g., kaolin, silica, or ellagic acid) are used in various combinations for the APTT test. Table 4 shows the major manufacturers and their APTT reagent preparations. The APTT test results are reported as direct time in seconds. Control plasma materials are also available, or the laboratory may use an in-house normal plasma pool. The APTT test is not as well standardized as the PT test. Different reagents can yield different results (anywhere from 25 s to 45 s); sensitivity also can vary. Besides measuring the integrity of the intrinsic system, the APTT test is most commonly used to monitor heparin therapy.

Table 4. PT/APTT Reagent manufacturers

Reagent name or trade name		
PT	APTT	Manufacturer
Thromboplastin C	Actin, Actin-FS	Dade
Brain thromboplastin	Thrombofax	Ortho
Simplastin	Platelin Plus	General Diagnostics
Liquid thromboplastin	APTT Reagent	Hyland
Thromborel	Pathrombin	Behringwerke
Thromboplastin	Cephalin	Helena
Neoplastine	CK-Prest	Stago
Thrombotest	Cephotest	Nyegaard
Thromboplastin with calcium	Activated Cephaloplastin	Merieux
Lyoplastin		Mochida
Calcium thromboplastin	PTT-Reagent	Boehringer

Other Screening Tests. *Thrombin time* is determined by adding thrombin [*9002-04-4*] to the patient's plasma. Times are abnormal if fibrinogen is abnormal or deficient or if thrombin inhibitors, such as heparin or fibrin degradation products (FDP), are present.

The *thromboelastogram* (TEG) is a means to measure the dynamics of the blood clotting process. The instrument cuvette is filled with venous blood, the blood is coated with paraffin oil, and a steel cylinder is inserted. The cuvette is placed into the thromboelastograph and put into torsional motion. As the blood begins to clot, fibrin threads, which cause the steel cylinder to move, are formed. This movement is detected via an optical system and recorded. Disorders in the coagulation system cause characteristic deviations from the normal thromboelastogram curve. This TEG test provides significantly more information than the other screening tests, but is not widely used because of the need for specialized instrumentation and the complexity of interpreting the results.

Euglobulin lysis time measures the status of the fibrinolytic system. Blood is allowed to coagulate in a tube. Normally the clot does not dissolve within 24 h; however, if it does dissolve within this period, the fibrinolytic system is assumed to be activated. The increase is clinically significant only if the clot dissolves within 1 h.

5.3. Specific Analytes

Assays for specific components of the coagulation–fibrinolytic system are made to diagnose the cause of abnormalities detected in preliminary screening tests. These assays may also be done to *monitor* patient response to therapy or to *counsel* a patient with a familiar genetic hemostasis disorder.

Essentially, all disorders of coagulation components are caused by *decreased biologic activity of specific proteins.* These disorders may be a result of defective protein synthesis, altered synthesis or rates of clearance from the circulation, or presence of pathologic inhibitors. Although immunologic testing may indicate normal analyte levels, biologic activity may still be decreased. Specific assays for biologic activity are not available for all components.

5.3.1. Coagulation Factors

Qualitative identification of an abnormal coagulation factor is needed prior to determining the actual factor activity and to differentiating between whether the factor is deficient or whether a circulating acquired inhibitor is present. If the screening test (PT or APTT) result is abnormal, the test is repeated with a 1 : 1 mix of test plasma and normal human plasma. If the test result is corrected by adding normal plasma, a factor deficiency is indicated; uncorrected test results suggest a circulating inhibitor. Further retesting with 1 : 1 mixtures of test plasma and aluminum hydroxide adsorbed plasma (or aged serum) can help pinpoint the deficient plasma factor.

Fibrinogen [*9001-32-5*] (Factor I). Fibrinogen is most commonly measured by the *Clauss method.* Test plasma is diluted 1 : 10 with veronal buffer, mixed with excess thrombin, and

then the clotting time is measured. Heparin and FDPs interfere with the test. Antisera and radioimmunodiffusion (RID) plates are also available for immunologic testing of fibrinogen.

Factors II – XII. These factors are measured by using a *modified PT* (factors II, V, VII, and X) and *APTT* (factors VIII, IX, XI, and XII) tests. Test plasma is diluted 1 : 10 with barbital buffer and mixed 1 : 1 with an appropriate factor-deficient plasma, and the clotting time is measured. Because these assays are based on the PT and APTT tests, complications, such as heparin interference or clot time shortening by elevated coagulation factors, may lead to erroneous results.

Alternatively, *synthetic substrate methods* are available for analyzing all factors. Several of these assays (factors II, VIII, and X) can be readily performed with commercial kits, whereas the rest require special reagents. Synthetic substrate assays afford improved sensitivity, specificity, and reproducibility over traditional clotting assays, but generally have not been fully evaluated in many pathological states, and some discrepancies versus clotting assays have been reported.

Factor XIII. Deficiencies in factor XIII are not detected by routine screening tests and must be recognized by *clinical symptoms.* Suspected deficiencies can be screened by testing *clot solubility* in 5 M urea; normal samples are stable whereas abnormal ones form clots that dissolve within 1 h. Heparin can interfere with this test. An alternative method uses 1 % chloroacetic acid, which speeds abnormal clot dissolution but is more susceptible to interference. Antisera are available for immunologic testing.

Prekallikrein [*9055-02-1*] (Fletcher Factor). Suspected deficiencies can be screened by running the *APTT test,* using kaolin or celite as activator and allowing a 10 min incubation. If this corrects the APTT time, then prekallikrein deficiency is probable. APTT activators that contain ellagic acid are usually insensitive to this deficiency. Quantification can be done by using the clotting assay described for factor XIII with prekallikrein deficient plasma or by using a commercial synthetic substrate kit. Antisera are available for immunologic testing.

High Molecular Mass Kininogen (Fitzgerald Factor). Suspected deficiencies show prolonged APTT times that are not corrected by increased incubation time; usually the patient does not have a history of overt bleeding. Quantification is done with a *clotting assay* (as described) and Fitzgerald factor deficient plasma.

Passovoy Factor. Suspected deficiencies show prolonged APTT times that are not corrected by increased incubation time; the patient has a history of bleeding problems and normal levels of other factors. Quantification is done with a *clotting assay* (as described) and passovoy factor deficient plasma.

5.3.2. Fibrinolytic Pathway

Plasminogen [*9001-91-6*] . The most common plasminogen assay is a *synthetic substrate method.* Plasminogen, activated by addition of either streptokinase or urokinase, hydrolyzes the substrate. The results agree well with the older, more laborious caseinolytic assay. Both RID plates and antisera are available for use in immunologic testing.

FDP. Fibrin and fibrinogen degradation products are readily measured with a *latex agglutination slide assay.* Latex particles coated with antifibrinogen antibodies form visible aggregates when reacted with serum samples containing FDP.

Special sample collection tubes containing thrombin and soybean trypsin inhibitor are used to remove cross-reactive fibrinogen from the sample and prevent in vitro formation of FDP by endogenous proteases after sample collection. Heparin can cause a positive bias because it prevents complete removal of fibrinogen. Batroxobin, a thrombin-like enzyme that is insensitive to heparin, may be substituted for thrombin with samples containing heparin.

A more sensitive, but technically demanding, procedure is the *tanned red cell hemagglutination inhibition immunoassay* (TRCHII), which uses human erythrocytes coated with fibrinogen. Serum (collected as described for the latex assay) is incubated with antifibrinogen antibody and then mixed with the coated erythrocytes. Presence of FDP in the test serum de-

creases visible agglutination. Both the latex particle and TRCHII assays are semiquantitative, and results are reported in titers (equal to the mass of the substance equivalent to a liter of standard solution). Different antibody preparations have different sensitivities to individual degradation products and, therefore, can cause test performance to vary.

5.3.3. Activators

Thromboplastin. A standard assay for thromboplastin activity is not available. The PT test can be modified by using excess normal human plasma and by making thromboplastin the limiting reagent to give an assay for thromboplastin.

Urokinase [*9039-53-6*] . *Synthetic substrates* are available that react directly with urokinase.

Streptokinase [*9002-01-1*] . The *synthetic substrate assay for plasminogen can be modified* to give an assay for streptokinase. Excess purified plasminogen is added to the reaction mixture; the sample that is used contains streptokinase, which is the limiting reagent.

5.3.4. Inhibitors

Two types of inhibitors are present in the human blood system: (1) *naturally occurring plasma proteins,* which are integral to normal hemostasis, and (2) circulating *acquired inhibitors,* which react against specific coagulation factors arising from a pathological cause. Acquired inhibitors can lead to bleeding problems and are differentiated from factor deficiencies by a mixing test (see Section 5.3.1). Typically these inhibitors react with factor VIII or are of the lupus anticoagulant type. Serial testing that uses the APTT assay or a 1 : 1 mix of test plasma with normal human plasma can differentiate the type of acquired inhibitor. The APTT is longer if an inhibitor to factor VIII is present, but is not changed with lupus anticoagulant-type inhibitors.

Factor VIII Inhibitor. Test plasma containing this inhibitor is mixed with normal human plasma and incubated; residual factor VIII activity is measured. The result is compared with a control plasma incubated for the same period of time; the control is needed to correct for the natural lability of factor VIII. The corrected residual factor activity is reported in Bethesda units.

Lupus Anticoagulant. Lupus anticoagulant-type inhibitors act on thromboplastin and can be measured with diluted thromboplastin, using a *modified PT test.*

Antithrombin III (AT III). The biologic activity of AT III is commonly measured by its *heparin-catalyzed inhibition of thrombin;* a synthetic substrate method is used. Bovine rather than human thrombin is recommended to prevent interference from heparin cofactor II. A variation of this method is to substitute factor Xa for thrombin, but limited clinical data are published for this variation. Both RID plates and antisera are available for immunologic testing.

α_1-Antitrypsin [*9041-92-3*] . Biologic activity can be measured by the *inhibitory effect of α_1-antitrypsin on trypsin or elastase;* a synthetic substrate method is used. This inhibitor is most commonly tested with RID plates or other immunologic methods.

β_2-Macroglobulin. Biologic activity can be measured indirectly through a synthetic substrate method that uses *trypsin.* β-Macroglobulin is most commonly tested with RID plates or other immunologic methods.

α_2-Antiplasmin. This compound is most commonly measured by its *inhibition of rapid plasmin;* a synthetic substrate method is used. Both RID plates and antisera are available for immunologic testing.

Protein C. Preliminary assays for biologic activity, which use synthetic substrate methods, have been developed. These analyses require specialized biochemical reagents and are only used in research laboratories. Most Protein C testing is done by ELISA or other immunologic assays.

5.4. Platelets

Normal platelet number and function are required for proper hemostasis. *Platelet number* is measured either manually with a microscope or automatically with an electronic or optical counter. The normal platelet count is 250 000 – 450 000/mm ^{3}.

Platelet function can be tested with the *bleeding time test.* A small incision is made on the patient's arm, usually using a template to improve test standardization, and increased venous pressure (5.3 kPa) is maintained with a blood pressure cuff. The time required until bleeding stops is measured; normal time ranges from 2 to 6 min. Prolonged time indicates abnormal vessel contraction, low platelet count, or abnormal platelet function. Drugs, such as aspirin, or von Willebrand factor deficiency can prolong bleeding time. This test may not detect coagulation disorders, such as hemophilia, because it measures the integrity of the initial platelet clot.

Platelet function can also be measured with a *platelet aggregometer.* Platelet-rich plasma is stirred in a cuvette, and the transmittance of light through the sample is measured. When an aggregating agent is added, the platelets aggregate, causing the plasma to clear, and the increase in light transmittance is recorded. Agents, such as ADP, thrombin, epinephrine, and ristocetin, induce the platelets to aggregate or cause them to release endogenous ADP. Abnormal platelet aggregation profiles can be indicative of various disorders, such as von Willebrand's disease, idiopathic thrombocytopenic purpura, and platelet storage pool disease, or of drug presence (aspirin, heparin, etc.).

Other specialized platelet function tests are sometimes used to determine platelet retention, adhesiveness, and clot retraction. Specialized tests for platelet factor IV or glycoprotein surface receptors are available to help diagnose specific disorders. These tests are normally performed by using specific immunologic reagents.

5.5. Control of Anticoagulant Therapy

5.5.1. Oral Anticoagulants

Oral anticoagulants act by preventing a vitamin K dependent carboxylation step in the synthesis of factors II, VII, IX, and X. This does not affect the quantities of the factors produced, but does result in them having no biologic activity. Management of the anticoagulant dose regulates the balance between active and inactive factor production.

The *PT test* is preferred for monitoring oral anticoagulant therapy as it is sensitive to three of the affected factors (II, VII, and X). Variation in the manufacture of thromboplastins used in this test results in wide variation sensitivity to the various factors, with resulting changes in the therapeutic range. A proposal to have manufacturers calibrate their thromboplastins with respect to international standards may eventually lead to improved standardization.

An alternative approach is to *control therapy on the basis of a single affected factor,* using a synthetic substrate method. This may improve specificity for the effect of the drug by eliminating nonspecific interferences that occur with the PT test. Comparison studies have shown good correlation between the PT test and factors II and X for patients on long-term therapy.

5.5.2. Heparin

Global Clotting Assays. Standard heparin [*9005-49-6*] therapy is usually controlled by the APTT test. Alternative assays in use include the thrombin clotting time and whole blood clotting time tests. For patients undergoing extracorporeal circulation, with its associated high heparin levels, the activated clotting time (ACT) is assumed to be the same as the APTT. This assumption is unreliable at high dose. Clotting assays, such as APTT and PT, ultimately rely on thrombin formation and are susceptible to various nonspecific interferences. They are also insensitive to low molecular mass heparin (M_r 6 000 – 20 000).

Specific Assays. Heparin can be assayed directly because of its ability to catalyze the AT III inhibition of thrombin or factor Xa. These assays can be classified as measuring either total heparin activity (when the assay uses excess AT III) or effective heparin activity (test plasma is the sole source of AT III). Typically these assays employ synthetic substrates.Factor Xa is the preferred enzyme reagent because it allows for measuring both standard and low molecular mass

heparin preparations. Data are not yet available on the relative clinical efficacy of these heparin-specific assays versus the global clotting assays.

6. Reagents for Nuclear Medicine

6.1. Nuclear Imaging (Radioscintigraphy)

Purpose. The object of nuclear medicine procedures is to *diagnose disease and dysfunction by external imaging of the distribution of a radioactive compound in the body* [88–91]. The radionuclides used in imaging procedures are selected from those that decay by emission of γ-rays, which penetrate the body and permit accurate and noninvasive external detection with imaging devices [92].

Diagnostic radiopharmaceuticals may be simple *radioactive ions* in aqueous solution or *labeled compounds*, which are radionuclide-containing inorganic, organic, or biologic molecules. Certain radiopharmaceuticals have biologic properties that permit accumulation, and therefore visualization, of the internal organs. Within these organs, areas of disease or decreased function may be detected as regions of lower concentration of radioactivity or *cold spots.* In other cases, such as in bone disorders, abnormal areas may accumulate radioactivity to a greater degree than normal tissue and appear as *hot spots.* In other procedures, radiopharmaceuticals are used to measure or visualize a *dynamic function,* e.g., blood flow through the heart, renal excretion, or pulmonary ventilation. In these procedures, the rate of accumulation of the radiopharmaceutical and clearance of activity is diagnostic of normal or abnormal function.

Because γ-emitting nuclides can be detected with such high sensitivity, doses of radiopharmaceuticals can be kept well below levels that produce any pharmacologic or adverse effects in the patient.

Typical Procedure. Diagnostic nuclear imaging procedures are performed in hospitals or nuclear medicine clinics that are licensed for radioisotope use. In most procedures, the radiopharmaceutical is administered to the patient intravenously, although other routes, such as oral administration or inhalation, are appropriate with certain agents. After administration, the diagnostic agent is permitted to distribute within the body for a specified period of time, usually from 10 min to 3 h. This is required for a sufficient accumulation of radioactivity in the target organ or site and sufficient clearance from the blood or immediately adjacent sites to provide adequate contrast. Typically, good images can be produced if the target to nontarget ratio of activity is 5 : 1 or greater.

After the appropriate time, the patient is positioned under an imaging device, the γ-camera, which can detect the spatial distribution of the radiopharmaceutical in the body. Most commonly, a single view (or multiple views) of the area of interest is obtained to provide a two-dimensional image of the organ. With newer rotating tomographic cameras, imaging data are obtained at preset angles around the body. A three-dimensional image of the organ is then reconstructed from the imaging data.

6.2. Detection Devices

Anger Camera. The most common imaging device in nuclear medicine is the Anger scintillation camera, which provides two-dimensional planar images for a variety of diagnostic applications. The *detection system* of the basic Anger camera is shown in Figure 1.

Figure 1. Schematic of the Anger scintillation camera
a) Source of γ-radiation; b) Collimator; c) NaI (Tl) Crystal; d) Light pipe; e) Photomultiplier tubes; f) Preamplifiers; g) Computing circuits.

The *collimator* (b) is a thick plate of high-density material, generally lead, which absorbs radiation. An array of channels is geometrically arranged over the surface. The role of the collimator is to limit the field of view and allow only photons emitted from a defined spatial location within the body to reach the detector crystal. Detection sensitivity and image resolution are a function of the distance of the collimator from the source of radiation, as well as a function of the collimator design.

The *thallium-activated sodium iodide crystal* (c), NaI(Tl), traps the γ-rays and converts them to small flashes of visual light, i.e., scintillations. These scintillations are subsequently converted from light to current flow by the *photomultiplier tubes* (e). In the next phase, the *computing circuit* (g), in combination with the photomultiplier array, determines the $x-y$ location of the scintillations occurring within the crystal.

A range of cameras, which offer various fields of view, is available commercially. The standard field of view (SFOV) camera can detect a field with a diameter of ca. 25 cm. The large field of view (LFOV) camera can image an area with a diameter of 35.6 – 41.9 cm, whereas a new extra large field of view camera (the jumbo camera) can image a 54.6 cm field. The particular advantage of large field cameras is that a whole body survey can be obtained rapidly with a single pass of the detector. The total camera system resolution of most state-of-the-art Anger cameras ranges from ca. 13 to 18 mm. However, if contrast is good, lesions of considerably smaller size can be detected.

SPECT Imaging. A limitation of current Anger cameras is that they provide only two-dimensional images of the three-dimensional object. Frequently underlying and overlying structures accumulate activity and obscure the image of the target organ or site. Advances in scintillation camera technology have resulted in single photon emission computed tomographic (SPECT) systems [93]. These systems use single- or multiheaded scintillation cameras, which provide multiple views at different angles of rotation around the subject. Computerized data collection then permits a reconstruction of a three-dimensional image or a slice-by-slice representation.

Positron Camera. Positron emission tomography (PET) involves the use of radiopharmaceuticals labeled with nuclides that decay by positron (positively charged electron) emission. In this decay process, a positron is emitted from the nucleus and is annihilated in a collision with a negatively charged orbital electron. In the annihilation reaction, the two particles are converted into two 8.19×10^{-14} J γ-rays, which travel away from each other at an angle of 180 °. In PET imaging, two opposed detectors simultaneously record the two high-energy γ-rays. Because only those γ-rays that strike the two opposed detectors simultaneously are recorded (coincidence counting), no collimator is necessary in a positron camera. Modern PET systems involve multidetector arrays arranged in a circle. The total system resolution of the multidetector PET camera is 7 – 10 mm. Consequently, both resolution and sensitivity of positron emission tomography is greater than that of single photon imaging.

Despite major imaging advantages of positron emission tomography, the procedure is currently limited to large medical research institutions. In addition to the considerable cost of modern PET systems ($> \$1\times10^6$), the positron emitting radionuclides of greatest interest (see Section 6.3) have exceedingly short half-lifes, e.g., ^{11}C, $t_{1/2} = 20$ min; ^{13}N, $t_{1/2} = 10$ min; ^{15}O, $t_{1/2} = 2$ min; and ^{18}F, $t_{1/2} = 110$ min. These isotopes must be produced by a cyclotron at the site of use. The establishment of a cyclotron facility and positron imaging laboratory typically requires an investment of $> \$2\times10^6$. In 1986 ca. 50 institutions worldwide had such facilities.

6.3. Radionuclides

6.3.1. Selection Criteria

The first consideration in selecting a γ-emitting isotope for use in conjunction with the Anger camera is its *decay scheme,* particularly the energy and abundance of its γ-emissions [94]. For good detection and collimation, the ideal isotope should emit γ-radiation with energy of $(1.6-3.2)\times10^{-13}$ J. Photons of lower energy are significantly attenuated, i.e., scattered within the body, and are poorly resolved by the camera; photons of energy $>6.4\times10^{-13}$ J penetrate

most collimators and flood the crystal with uncollimated radiation. The isotope should also be free of any "useless" radiation, such as particulate radiation (α or β) or γ-photons, which are too high or too low in energy, as these may degrade the image and also contribute significantly to the radiation dose received by the patient.

A further consideration is the *half-life* of the radionuclide. In most procedures currently in use, imaging is performed between 10 min and 4 h after administration of the radiopharmaceutical. Therefore, nuclides with short half-lifes, such as ^{99m}Tc and ^{123}I, are generally the most appropriate. Isotopes with ultrashort half-lifes, i.e., $t_{1/2} < 1$ h, and isotopes with intermediate half-lifes, i.e., $t_{1/2} > 4$ d, are not ideal. γ-Emitting radionuclides of greatest medical interest are shown in Table 5.

Table 5. γ-Emitting radionuclides for diagnostic imaging

Nuclide	$t_{1/2}$, h	γ-Energy, $\times 10^{-14}$ J
Ideal	~ 4	1.6 – 3.2
^{99m}Tc*	6	2.24
^{123}I	13	2.55
^{203}Pb	52	4.47
^{111}In	68	2.77
		3.96
^{97}Ru	70	3.46
^{201}Tl	73	1.1 – 1.3
^{67}Ga	78	1.49
		2.96
		4.81
		6.31

* m = Metastable.

Some nuclides are produced by nuclear reactors or particle accelerators, such as cyclotrons or linear accelerators. Other short-lived and ultrashort-lived nuclides are obtained from the decay of a parent nuclide through the use of a radioisotope generator [95]. The generator is generally a chromatographic column packed with media, such as alumina or an organic or inorganic ion-exchange resin, on which the parent isotope is adsorbed. As the parent decays, the daughter isotope concentration increases on the column and may be eluted with a suitable solvent, generally an aqueous solution. A generator, therefore, permits the delivery of a short-lived daughter nuclide by using the longer half-life of the parent.

6.3.2. ^{99m}Tc

^{99m}Tc [*14133-76-7*]is the isotope of choice because of its *excellent imaging characteristics* and its *ready availability*. The chemistry of technetium is complex but versatile, and a wide range of ^{99m}Tc radiopharmaceuticals is both known and practical.

Technetium [^{99m}Tc] is obtained from its parent isotope ^{99}Mo, which is a product of nuclear fission. Molybdenum [^{99}Mo] decays by γ-emission, with $t_{1/2} = 66.5$ h, to the isotope of greatest medical interest, the metastable ^{99m}Tc, which decays to ^{99}Tc by emitting a single γ-photon (2.24×10^{-14} J, $t_{1/2} = 6$ h).

Although ^{99}Tc is a β-emitter, the quantity of this long-lived radionuclide ($t_{1/2} = 2.1 \times 10^5$ years) present in radiopharmaceutical preparations is so low that solutions are considered nonradioactive.

Most commonly, ^{99m}Tc is delivered as a ^{99}Mo – ^{99m}Tc radionuclide generator. The parent isotope is adsorbed on an alumina column and a maximum concentration of ^{99m}Tc forms every 23 h. Typically, the generator is eluted once daily with sterile physiologic saline solution, and the resulting ^{99m}Tc eluate is available for preparing other radiopharmaceutical compounds.

The ^{99m}Tc eluate contains $^{99m}Tc^{7+}$ as $^{99m}TcO_4^-$, which is used directly for some diagnostic applications; however, most radiopharmaceutical uses of this nuclide require the preparation of other ^{99m}Tc-labeled compounds. A wide variety of ^{99m}Tc radiopharmaceuticals can generally be prepared by using commercially available kits, which contain chemicals required to reduce $^{99m}Tc^{7+}$. The reduced ^{99m}Tc is subsequently complexed with an organic molecule, which produces the radiopharmaceutical with the desired avidity for an organ or a disease site. Typically, the desired radiopharmaceutical

is prepared on the day of use with a commercially available freeze-dried kit and ^{99m}Tc eluate from a ^{99}Mo – ^{99m}Tc generator. The ^{99m}Tc radiopharmaceutical forms rapidly and quantitatively, and no further purification is required prior to administration [96].

The γ-energy of ^{99m}Tc is ideally collimated and detected by the Anger camera system. Because ^{99m}Tc is a pure γ-emitter with a short half-life, doses of 3 – 30 mCi are acceptable without significantly irradiating the patient. Technetium (^{99m}Tc) is the isotope of choice as long as imaging can be completed within 24 h of the administration of the agent and the desired agent can be prepared satisfactorily.

Table 6. Ultrashort half-lifed generator-produced nuclides for diagnostic imaging

Nuclide	$t_{1/2}$, s	γ-Energy∗, $\times 10^{-14}$ J
^{191m}Ir	4.90	2.07
^{81m}Kr	13.00	3.04
^{195m}Au	30.00	3.46
^{82}Rb	75.00	8.19

∗ Of major imaging photons.

6.3.3. Other γ-Emitters

Among alternatives to ^{99m}Tc, ^{123}I [*15715-08-9*] (see Table 5) isan attractive isotope for general use. A singular advantage of ^{123}I, in addition to its ideal energy, is the availability of well-established iodination reactions. Iodine can be easily added to a wide variety of molecules without disturbing the biologic properties of these compounds. Because no generator system is possible for ^{123}I, it must be prepared frequently with a cyclotron. In addition, most low-energy cyclotrons produce ^{123}I contaminated with 3 – 5 % of the longer lived ^{124}I. This radionuclide cannot be separated from ^{123}I by conventional chemical means and, when present in higher quantities, may degrade the image (because of high-energy γ-photons) as well as increase the radiation dose to the patient.

For those applications that require imaging 24 h or longer after administration of the agent, other radionuclides with intermediate half-lifes may be considered. Most attractive among these is ^{111}In [*15750-15-9*] (see Table 5), whichis available in good abundance; ^{203}Pb [*14687-25-3*] and ^{97}Ru [*15758-35-7*]also are suitable. However, because In, Pb, and Ru ions are not present inmolecules of biologic interest, their use requires preparing novel radio-labeled compounds.

In newer applications, γ-emitting radionuclides with $t_{1/2}$ <10 min have been used for studying processes that have very rapid biokinetics, such as blood flow, cardiac-wall motion, and pulmonary ventilation. These *ultrashort-lived nuclides* (see Table 6) have the unique advantage of producing low radiation exposure to the patient, which permits administration of high millicurie doses. In addition, because the radioactivity decays within minutes, repeat studies may be performed quickly.

6.3.4. Positron Emitters

Large medical centers with positron-imaging capabilities and a nuclear reactor or cyclotron on site can use positron-emitting nuclides for medical diagnosis. *Cyclotron-produced* isotopes, such as ^{11}C [*14333-33-6*] ($t_{1/2}$ = 20.50 min), ^{13}N [*13981-22-1*] ($t_{1/2}$ = 9.95 min), ^{15}O ($t_{1/2}$ = 2.05 min), and ^{18}F [*13981-56-1*] ($t_{1/2}$ = 110.00 min), have been used to label biologic molecules to produce true physiological tracers that retain native biologic activity. Because of the short half-lifes, on-site production capability for these positron isotopes is required.

If a cyclotron is not available on site, two *generator-produced,* positron-emitting isotopes are available in radiochemical (not radiopharmaceutical) grade: ^{68}Ga [*15757-14-9*]($t_{1/2}$ = 68.00 min) and ^{82}Rb [*14391-63-0*] ($t_{1/2}$ = 1.30 min).

6.4. Diagnostic Radiopharmaceuticals

6.4.1. Heart Imaging

Diagnostic agents are available for use in studying the functions of the heart. *Thallium* [^{201}Tl^{+}], an analogue of K^{+}, is efficiently extracted by the myocardium and accumulates in the heart muscle in proportion to its concentration in the blood. When viewed from the left anterior oblique (LAO) position relative to the chest, the walls of the left ventricle, in a normal subject, appear as a “donut” (Fig. 2A). In a patient with significant coronary artery disease, blood flow may be entirely adequate at rest; however, with

exercise (or pharmacologic) stress, the affected regions may appear transiently to have inadequate blood flow, appearing as a "broken donut" (Fig. 2B). Old myocardial infarctions appear as cold spots both at rest and stress.

The wall motion and blood pumping functions of the left and right ventricle can be studied by using ^{99m}*Tc*-labeled red blood cells (RBCs). Typically, the patient receives a first dose of tin (II) pyrophosphate ($Sn_2P_2O_7$), which is taken up by the RBCs. The Sn^{2+} reduces $^{99m}TcO_4^-$, which is administered 30 min later. To study the heart at various phases of the contractile cycle, the γ-camera is controlled by an electrocardiograph. Quantitative measurements of the injection fraction may be obtained, in addition to qualitative observations of wall motion during contraction.

Figure 2. Heart images (^{201}Tl) of a patient with coronary artery disease (LAO views)
A) At rest; B) After exercise stress.

In some cases, ventricular function is assessed by observing the first passage of a bolus of radioactivity through the heart. Any ^{99m}Tc radiopharmaceutical (except one that is extracted by the lungs) may be used for first-pass studies. The generator-produced ultrashort-lived isotope ^{195m}Au (see Table 6) has been used for multiple-repeat first-pass studies. Because of its high γ-energy, it can be used simultaneously with ^{201}Tl or ^{99m}Tc. A disadvantage, however, is that the short half-life of the parent nuclide, ^{195m}Hg ($t_{1/2} = 40$ h), limits the shelf life of the generator to 3 d. The ^{195m}Hg – ^{195m}Au generator has recently become commercially available in Europe.

Fatty acids labeled with ^{123}*I* are available in Europe for clinical studies of aerobic metabolism in the myocardium. Research has shown that ^{11}*C-palmitic acid* can give early and specific information on developing cardiomyopathies, as well as ischemic disease.

6.4.2. Brain Imaging

Use of radiopharmaceuticals, such as $^{99m}TcO_4^-$, ^{99m}Tc-DTPA (diethylenetriamine-*N,N,N′,N″,N″*-pentaacetic acid) [*80908-06-1*], and ^{99m}Tc-glucoheptonate for brain imaging-has declined because of increased availability of *computerized transaxial tomography* (CAT scanning). Radiopharmaceuticals are still in use, however, and provide information on the integrity of the blood brain barrier. Extravascular accumulation of activity suggests a brain tumor, abscess, or other pathology.

Some experimental radiopharmaceuticals currently under development for brain imaging are discussed in Section 6.5.

6.4.3. Bone Imaging

The *agents of choice for bone imaging* are ^{99m}Tc-labeled MDP (methylene diphosphonate), EHDP (ethane 1-hydroxy-1-diphosphonate), and HMDP (hydroxymethylene diphosphonate) although ^{99m}Tc-pyrophosphate is also used. All can be *prepared from commercially available kits.*

In normal subjects, these agents are quickly absorbed by bone (but not by blood and soft tissue) so that images of the skeleton can be produced within 1 h after administration. In patients with bone disorders, areas with low concentration indicate bone destruction or necrosis. Other lesions, such as septic or aseptic inflammation, fracture healing, and tumor growth, are detected as areas of high radioactivity. This is probably because of increased bone blood flow and increased extraction efficiency in those areas of higher metabolic activity.

An image of a patient with multiple tumor metastases is shown in Figure 3. Nuclear medicine procedures provide earlier detection of metastatic lesions, where no significant bone destruction or density change has occurred, than does conventional radiology (X-ray). The image also illustrates the use of a wide field of view camera to produce a whole body survey for diagnosis of occult lesions.

6.4.4. Lung Imaging

Imaging of lung perfusion and ventilation, either separately or together, is *used to diagnose pulmonary disorders.* Suspensions of labeled macroaggregates of albumin (^{99m}Tc-MAA) or human albumin microspheres (^{99m}Tc-HAM) are injected intravenously to study the perfusion of the lung capillary bed. If the vascular system is obstructed, the concentration of activity in the involved lung segments is decreased. Although this technique is helpful in diagnosing pulmonary embolism, abnormal lung perfusion is nonspecific and may occur with other disorders.

Figure 3. Bone image (^{99m}Tc-MDP) of a patient with multiple metastases to the skeleton (seen as hot spots)

Three *radioactive noble gases* have been used to study pulmonary ventilation: ^{127}Xe [*13994-19-9*], ^{133}Xe [*14932-42-4*], and ^{81}Kr [*15678-91-8*]. Xenon [^{133}Xe] is widely used clinically for single-breath studies and also for lung volume and washout imaging. The physical characteristics of ^{127}Xe are preferable to those of ^{133}Xe, but availability is more limited. Krypton [^{81m}Kr], a generator-produced isotope with a 13-s half-life, can be used for single breath imaging studies.

Radioactive aerosols, prepared with ^{99m}Tc agents, have been used in place of the radioactive noble gases for ventilation studies. The advantages of ^{99m}Tc aerosols include the ready availability and optimum characteristics of ^{99m}Tc and the longer residence time of the agent in the lung. Because the radioactive aerosol deposits in the smaller bronchi and alveoli, multiple images in several projections may be obtained. However, with chronic obstructive pulmonary disease, deposition of the aerosol in the major airways may be irregular, making interpretation of images difficult.

Combined ventilation and perfusion studies are frequently used to differentiate the perfusion disorders of pulmonary embolism from obstructive airway disorders.

6.4.5. Hepatobiliary Imaging

After intravenous administration, hepatobiliary imaging agents are rapidly cleared from the blood by the hepatocytes, or polygonal cells, which comprise 60 % of the liver mass in humans. The radiopharmaceuticals are then concentrated in the bile, transiently stored in the gall bladder, and excreted via the bile ducts into the small intestine. If all of the organs, i.e., the liver, gall bladder, bile ducts, and intestines, are not visualized sequentially, or if transit is delayed, the study is abnormal. If no activity appears in the intestinal tract, even after a prolonged period of time, complete obstruction of the bile duct is likely. Nonvisualization of the gall bladder in a patient who has been fasting for several hours suggests acute cholecystitis. Poor blood clearance and poor liver uptake is consistent with either primary hepatocellular obstruction or biliary obstruction. In jaundiced patients, serum bilirubin competes for the anion receptor on the hepatocyte membrane, resulting in decreased liver uptake and increased renal clearance of the radiopharmaceutical.

A series of ^{99m}Tc complexes of *N*-(2,6-dimethylphenylcarbamoylmethyl)iminodiacetic acid [*59160-29-1*] (HIDA) and its derivatives have been developed.

HIDA, R = $-CH_3$

Complexes of ^{99m}Tc with two HIDA derivatives, where R is ethyl or isopropyl, have been used extensively in patients in Europe and the United States. Other derivatives, e.g., the 3-bromo-2,4,6-trimethyl analogue of HIDA, have also been used experimentally.

6.4.6. Reticuloendothelial System

Radioactive colloids with particle sizes $<3\,\mu$m in diameter have been used to visualize major organs of the reticuloendothelial (RE) system, i.e., the liver, spleen, and bone marrow. After intravenous injection, the colloidal suspensions are rapidly extracted from the blood by phagocytosis. In the presence of decreased hepatic mass, decreased hepatic blood flow, or focal lesions within the liver, regional hepatic activity decreases and the activity in the spleen and bone marrow increases.

The ^{99m}*Tc-sulfur colloid* is the most widely used agent for RE imaging. A kit for the instant ^{99m}Tc labeling of a preformed colloid, is commercially available.

6.4.7. Renal Imaging

Three classes of radiopharmaceuticals have been employed for studying renal function. *2-Iodohippuric acid* [*147-58-0*], *labeled with* ^{131}*I* [*1203-90-3*], *or* ^{123}*I* [*54378-29-9*], is the only commercially available agent for estimating effective renal plasma flow. The glomerular filtration rate may be measured with radioactive metal chelates, e.g., ^{99m}Tc-DTPA.

Renal imaging is most frequently performed with ^{99m}*Tc-labeled glucoheptonate, 2,3-dimercaptosuccinic acid* [*75014-98-1*] *(DMSA), or DTPA*. All of these agents are cleared rapidly from the blood into the urine; however, with glucoheptonate and DMSA, sufficient activity is retained within the kidneys to permit visualization of the renal cortex and the collecting system for several hours.

6.4.8. Malignant and Inflammatory Regions

Gallium ($^{67}Ga^{3+}$) [*14119-09-6*] has been used to image and monitor the recurrence of soft tissue tumors, especially lymphomas, malignant melanomas, testicular and leukemic tumors, and sites of Hodgkin's disease. When injected intravenously, ^{67} Ga binds to transferrin and to other circulating Fe-binding proteins. The plasma clearance of ^{67}Ga is slow; ca. 25 % is excreted in the urine and feces in the first week after injection. Because of its high intestinal activity, which may be decreased by the use of laxatives and enemas, ^{67}Ga images thoracic and neck lesions generally better than abdominal sites. Typically, ^{67}Ga imaging is performed between 24 and 72 h after injection, depending on the need for background clearance from various sites.

^{67}Ga has been used more frequently for detecting abscesses and focal inflammatory lesions. The nuclide is known to concentrate in recent surgical incisions and in cases of acute thyroiditis, pneumonia, turberculosis, sarcoidosis, inflammatory cardiomyopathy, pyelonephritis, and osteomyelitis.

Although it continues to be useful, the *disadvantages* of ^{67}Ga include its long half-life, high-energy γ-emission, slow plasma and abdominal clearance, and the inability to differentiate tumors from inflammatory lesions.

More recently, an *uncharged lipophilic complex of* ^{111}*In with oxine* (8-hydroxyquinoline) has been used as a nonspecific label for blood cells. Populations of leukocytes, especially neutrophils, can be labeled in vitro with ^{111}In-oxine in a suspension containing only limited plasma proteins. Although separating and labeling leukocytes is time-consuming, ^{111}In-oxine is advantageous over ^{67}Ga. The labeled leukocytes concentrate in inflammatory lesions and can be optimally imaged within 24 h; they are not eliminated via the intestine. The specificity of abscess detection with ^{111}In-labeled leukocytes is >95 %.

6.5. Experimental Agents

Heart Imaging with ^{99m}Tc Agents. Extensive research in both academic and industrial laboratories has been directed to developing new radiopharmaceuticals for diagnostic imaging. In the area of diagnostic nuclear cardiology, new

^{99m}Tc agents for the study of myocardial perfusion are being sought to replace ^{201}Tl, whose isotopic properties (low γ-energy, long half-life) are nonideal. A series of ^{99m}*Tc-isonitrile complexes,* which concentrate in the myocardium in proportion to regional blood flow, have been reported [97]. The borders of the ventricular wall can be well resolved with these complexes because of the superior characteristics of ^{99m}Tc and its higher permissible dose. Therefore, these agents may be useful for simultaneous studies of both myocardial perfusion and ventricular function, which currently require two separate procedures.

Brain Perfusion Imaging. Radiopharmaceuticals have been studied for regional cerebral brain perfusion [98]. *N-Isopropyliodoamphetamine* labeled with ^{123}*I* (**2**) and a related amine, ^{123}*I-HIPDM* (*N,N, N′*-trimethyl-*N′*-[2-hydroxyl-3-methyl-5[^{123}I]-iodobenzyl]-1,3-propanediamine), (**3**) distribute in the brain in proportion to regional blood flow. These compounds may be used for single photon emission computed tomographic (SPECT) imaging of the brain because their residence time in the brain is long and their ability to differentiate gray-white matter is good.

There has also been considerable interest in developing ^{99m}Tc-labeled agents with properties analogous to ^{123}I-IMP (*N*-isopropyl-4-[^{123}I] iodoamphetamine). The ^{99m}Tc complexes of HMPAO ([^{99m}Tc]-oxo-3,6,6,9-tetramethyl-4,8-diazaundecane-2,10-dionedioxime) [*99944-78-2*] (**4**) [99]and NEP ([^{99m}Tc]-oxo-3,6-diaza-1,8-dithio-1,1,5,5,8,8-hexamethyl-3-*N*-piperidinylethyloctane) [*67-43-6*] (**5**) [100] appear promising for brain imaging studies.

Specific Brain Receptors. Extensive research has been directed toward developing and using *positron-emitting radiopharmaceuticals* that will image specific brain receptors. An example is ^{11}C-labeled *N*-methylspiperone, which is used in vivo to image dopamine receptors [101]. These and other agents may provide means for the noninvasive quantitation of specific receptors and for the study of their function in health and disease. It has been suggested that receptor-specific radiopharmaceuticals may also be useful for the objective diagnosis of senile dementias and psychiatric disorders as well as for drug monitoring.

Brain Metabolism. ^{11}*C-2-Deoxyglucose* and ^{18}*F-2-deoxyglucose* have been used experimentally in animals and humans to measure brain metabolism in disorders, such as stroke, epilepsy, and senile dementias, as well as in normal volunteers undergoing sensory stimulation.

Monoclonal Antibodies. Advances in biotechnology led to new areas of radiopharmaceutical research. Monoclonal antibodies targeted toward melanomas, as well as toward tumors of the lung, breast, and colon, are being explored as *carriers of diagnostic and therapeutic radionuclides.* Figure 4 shows the localization of a murine antihuman breast carcinoma antibody conjugated with ^{99m}Tc-metallothionein in a mouse bearing a human breast tumor [102].

Therapeutic Agents. Therapeutic nuclides are being studied because of the anticipated greater specificity of radiopharmaceuticals based on monoclonal antibodies. The therapeutic nuclides of greatest interest (see Table 7) are β-emitters with sufficient β-energy to produce a cytotoxic effect with a radiation range of several cell diameters.

Table 7. Nuclides for therapeutic applications

Nuclide	$t_{1/2}$, d	β-Energy (max), $\times 10^{-14}$ J
^{90}Y	2.7	3.64
^{188}Re	0.71	3.40
^{32}P	14.3	2.74
^{111}Ag	7.5	0.40
^{131}I	4.15	

Figure 4. Detection of a subcutaneous human breast tumor in a mouse with the B6.2 antibody conjugated with ^{99m}Tc-metallothionein
A) Antigen positive; B) ^{125}I-Antibody; C) ^{99m}Tc-Antibody.

6.6. Quality Control

Radiopharmaceuticals used in diagnostic and therapeutic procedures must meet most requirements for drugs and injectables. Agents must be sterile, free of compounds that cause fever, free of foreign matter, and well labeled. Simple and rapid thin-layer and paper chromatographic procedures have been available for detecting unreacted $^{99m}TcO_4^-$ and reduced hydrolyzed $^{99m}TcO_2$ in radiopharmaceutical solutions [103]. Newer TLC and HPLC procedures have been employed to assess the radiochemical purity of radiopharmaceutical solutions, i.e., the presence of a single, defined radiochemical compound.

Biodistribution as well as toxicological tests are generally performed on random samples from new lots of radiopharmaceuticals. Although these tests are necessary, the rate of adverse reactions to radiopharmaceuticals is low because of the lower administered doses of chemicals employed in diagnostic procedures as compared to typical therapeutic doses. From 1976 to 1979, the number of adverse reactions reported to the Registry of the Society of Nuclear Medicine was ca. 1 – 6 (per 100 000), of which only 3 % were severe.

In addition, routine quality control monitoring of the scintillation camera system is required. The pulse height analyzer is adjusted to give a symmetric window about the primary photo peak corresponding to the nuclides to be imaged. Uniformity of detector response and checks for linearity and spatial distortion, as well as good spatial resolution, are performed daily prior to beginning studies on patients.

6.7. Dosimetry

The administration of isotopes to patients for diagnostic studies is limited by the *potential radiation damage* that these isotopes can cause to various organs and tissues. The radiopharmaceutical, which the target tissue absorbs, is the primary source of this radiation. In addition, the target tissue can be irradiated by other proximal organs if they contain sufficient radioactivity. The amount of the absorbed dose is determined by the concentration of activity and by the residence time of the radiopharmaceutical in the target and proximal sites. For most radionuclides used for diagnostic purposes (which are substantially free of particulate radiation), the dose to the patient is in direct proportion to the half-life of the radionuclide. Therefore, short-lived and ultrashort-lived radionuclides deliver lower doses of radiation per millicurie administered. A significant limitation is placed on the permissible radioactivity dose of intermediate

half-lifed radionuclides because of their higher absorbed radiation dose per millicurie. Standard methods for performing internal dose calculations are described in the publications of the Medical Internal Radiation Dose (MIRD) Committee of the United States Society of Nuclear Medicine [104].

1. Introduction

Dialkyl sulfates **1** are neutral esters of sulfuric acid and aliphatic alcohols. The corresponding monoesters **2** (alkyl hydrogensulfates, monoalkyl sulfates) are known as alkylsulfuric acids. They are available only as the stable alkali metal salts. Cyclic sulfates **3** (alkylene sulfates) represent a special group of neutral sulfuric acid esters. They result from the reaction of one molecule of a diol with one molecule of sulfuric acid.

1

2

3

where R = alkyl

The most commercially important dialkyl sulfates, dimethyl sulfate [*77-78-1*] and diethyl sulfate [*64-67-5*], were first prepared in 1835 by Dumas and Peligot, who distilled a mixture of sulfuric acid and the corresponding alcohol. The general applicability of dimethyl sulfate as an alkylating agent was recognized by Ullmann and Wenner in 1900. Around this time, commercial production of dimethyl sulfate from sulfur trioxide and dimethyl ether began in Lyon, France.

The alkali metal salts of higher alkylsulfuric acids (fatty alcohol sulfates) are important surfactants and are not treated in this article (see → Laundry Detergents, → Surfactants).

2. Physical Properties

Up to dihexyl sulfate, the dialkyl sulfates are liquids at room temperature. They are completely miscible with polar organic solvents and aromatic hydrocarbons, but their solubility in water is poor. The first members of the homologous series of dialkyl sulfates are only partially miscible with saturated hydrocarbons. Boiling points are relatively high. Some physical properties of symmetrical dialkyl sulfates are listed in Table 1.

Dimethyl sulfate forms an azeotrope with water (73 wt % water, *bp* 98.6 °C).

Solubility of dimethyl ether in dimethyl sulfate at 0.1 MPa [9]:

t, °C	0	10	20	30	40	50
Solubility wt %	6.3	5.2	4.3	3.6	3.0	2.6

The lower cyclic sulfates have comparatively high melting points, which decrease with increasing molecular mass (see Table 2).

Alkylsulfuric acids, which are usually described as viscous oils, are unstable compounds.

*

They are strong acids. Methyl hydrogensulfate [*75-93-4*], for example, is readily soluble in water; it is strongly dissociated in aqueous solution [10]. The preparation of neopentyl hydrogensulfate as a crystalline solid which melts on warming to room temperature has been described [11]. The alkali and alkaline earth metal salts of alkylsulfuric acids are stable, crystalline compounds, which often contain water of crystallization. The ammonium salts have well-defined melting points (ammonium methyl sulfate [*19803-43-1*], *mp* 135 °C; ammonium ethyl sulfate [*513-13-3*], *mp* 97 °C; ammonium *n*-propyl sulfate, *mp* 132 °C) and can be used to identify the alcohols.

3. Chemical Properties

Pure dialkyl compounds are not acidic. Traces of acid can be removed with cold hydrogen carbonate solution. Dimethyl sulfate may be stored for several days over dry anhydrous sodium carbonate, dry calcium oxide, or dry calcium carbonate, without undergoing any changes.

An equilibrium exists between monoalkyl sulfates and dialkyl sulfates:

$$2\,RHSO_4 \rightleftharpoons R_2SO_4 + H_2SO_4$$

This equilibrium can be shifted completely to the right by chemical binding of the sulfuric acid or by distilling the dialkyl sulfate.

Even at temperatures as low as 100 °C, unsymmetrical dialkyl sulfates are converted partially into the symmetrical esters:

$$2\,RR'SO_4 \rightleftharpoons R_2SO_4 + R'_2SO_4$$

Above 100 °C, acidic decomposition products such as $RHSO_4$ and SO_3 also form.

Dialkyl sulfates undergo acid- or base-catalyzed hydrolysis. In the acid-catalyzed reaction, free sulfuric acid forms rapidly. In alkaline solution, only the alkali metal salt of the alkylsulfuric acid is produced at room temperature. Higher temperatures are necessary for further hydrolysis. The alkyl groups are split off as alcohols, but small amounts of the corresponding ethers may also form.

Dimethyl sulfate is hydrolyzed slowly in cold water, but at 50 °C it takes 20 min to produce a 99.9 % methylsulfuric acid and methanol [12]. Further hydrolysis leads to sulfuric acid and methanol.

The most important property of dialkyl sulfates is their ability to transfer alkyl groups to other molecules (for examples, see Chap. 8). Reactivity decreases with increasing chain length. In unsymmetrical dialkyl sulfates, the shorter alkyl group reacts before the longer one. Above 160 °C, the lower alkyl sulfates react with metal oxides, halides, carbonates, and other inorganic compounds to form metal sulfates.

Under ultraviolet light and at high temperature, one methyl group of dimethyl sulfate can be chlorinated to yield the monochloro derivative, which is more reactive than dimethyl sulfate. In alkylation, only the chloromethyl group is transferred.

Alkylsulfuric acids are hydrolyzed in water or aqueous mineral acid to sulfuric acid and the corresponding alcohol. The alkali-metal salts serve as mild alkylating agents. Alkyl fluorosulfates, $ROSO_2F$, can be prepared readily from dialkyl sulfates and fluorosulfuric acid; they have greater alkylating potential than dialkyl sulfates [13].

4. Production

4.1. From Ethers and Sulfur Trioxide

The addition of sulfur trioxide to dimethyl ether is used industrially for the production of dimethyl sulfate.

$$(CH_3)_2O\,(g) + SO_3\,(l) \longrightarrow (CH_3)_2SO_4$$

$$\Delta H_{76\,^\circ C} = -92 \pm 7\,\text{kJ/mol}$$

The reaction is carried out in water-cooled, vertical aluminum or stainless steel tubes (diameter, 0.2 m; height, 4 m). In a continuous process at ca. 70 °C, stoichiometric quantities of liquid sulfur trioxide and gaseous dimethyl ether are fed from the top and bottom, respectively, into the dimethyl sulfate that is already present. The two reactants quickly form an acidic adduct, which slowly rearranges to the neutral ester. The product drawn off from the bottom of the tubes still contains a considerable amount of the acidic adduct. To achieve a quantitative rearrangement, the product is held at 70°C for several hours. A tower and its associated holding vessel have an output of up to 120 kg of dimethyl sulfate per hour [14], [15].

Technical-grade dimethyl sulfate contains small amounts of acidic compounds: water leads to formation of an equivalent amount of sulfuric acid; methanol introduced with the dimethyl ether results in methylsulfuric acid; and saturated hydrocarbons present in the dimethyl ether can be converted to sulfonic acids. Technical-grade dimethyl sulfate may also contain small amounts of dimethyl ether. Most of the impurities can be removed by vacuum distillation over anhydrous sodium sulfate.

This process is unsuitable for higher dialkyl sulfates because ethers with carbon atoms that are not bound to either oxygen or chlorine will undergo oxidation.

4.2. From Olefins and Sulfuric Acid

Sulfuric acid can add to the double bond of olefins:

$$2(CH_3)_2C{=}CH_2 + H_2SO_4 \longrightarrow [(CH_3)_3CO]_2SO_2$$

An excess of olefin leads almost exclusively to formation of the dialkyl sulfate. Further addition of sulfuric acid results in a decrease in the concentration of dialkyl sulfate and an increase in the concentration of alkylsulfuric acid [16].

Generally, tertiary olefins react much more readily than secondary or primary ones. According to Markovnikov's rule, the hydrogen of sulfuric acid always adds to the carbon atom with

the greater number of hydrogen atoms. Therefore, even olefins with a terminal double bond do not form *n*-alkyl sulfates.

The reaction of olefins in aqueous sulfuric acid leads not to a single product, but to a mixture of dialkyl sulfate, alkylsulfuric acid, sulfuric acid, water, alcohol, ether, and olefin. The mixture is characterized customarily by the concentration of acid used and the molar ratio of absorbed olefins. A higher olefin pressure and a higher sulfuric acid concentration favor formation of the corresponding dialkyl sulfate. Thus, the reaction between ethylene and 96 % sulfuric acid at standard pressure leads almost exclusively to ethyl hydrogensulfate, whereas anhydrous sulfuric acid at 0.35 MPa (3.5 bar) yields a mixture of 35 % diethyl sulfate and 51 % ethyl hydrogensulfate. At 1 MPa (10 bar), 62 % of diethyl sulfate and 30 % of ethyl hydrogensulfate are formed [17].

Sulfuric acid always causes some polymerization of olefins. Therefore, the sulfuric acid concentration and the reaction temperature should be kept as low as possible. Indeed, the reaction is most often carried out at or below ambient temperature.

The reaction of olefins with sulfuric acid is used industrially to extract isobutene [*115-11-7*] (2-methylpropene) from mixtures of C_4 hydrocarbons (65 % sulfuric acid) (→ Butenes); 80 % sulfuric acid is required to remove isoamylene [*563-45-1*] (3-methyl-1-butene) from mixtures of C_5 hydrocarbons [18].

4.3. From Alcohols and Chlorosulfuric Acid

The reaction between chlorosulfuric acid [*7790-94-5*] and an alcohol at low temperature yields the corresponding alkylsulfuric acid [19].

$$\mathrm{ROH + ClSO_3H \longrightarrow ROSO_3H + HCl \text{ where } R = alkyl}$$

The alkylsulfuric acid cannot be isolated by distillation because it is less volatile than other constituents and rearranges rapidly in the acidic environment. Crystalline methylsulfuric acid (*mp* − 30 to − 35 °C) is obtained if the reaction is carried out at − 40 °C and the hydrogen chloride generated is driven off with nitrogen [10].

Reaction between an alcohol and amidosulfuric acid leads directly to the ammonium salt of the corresponding alkylsulfuric acid.

Conversion of alkylsulfuric acids into dialkyl sulfates by vacuum distillation produces high yields only with methylsulfuric acid [20].

$$\mathrm{2\,RHSO_4 \rightleftharpoons R_2SO_4 + H_2SO_4}$$

The isolation of dialkyl sulfates from the equilibrium mixture progresses more smoothly if a neutral sodium salt is added, which binds the liberated sulfuric acid as sodium hydrogen sulfate [21]. The following procedure is used to prepare diethyl sulfate:

Ethylsulfuric acid (1100 kg, *d* 1.41 at 15 °C) is distilled under vacuum (0.65 kPa) in an enameled, stirred tank of 3-m^3 capacity over 1950 kg of anhydrous sodium sulfate. The condenser and recipient vessel are made of aluminum. The yield is 580 kg of diethyl sulfate (99.8 % purity), which is equivalent to 86 % of the theoretical yield.

The drawback of such processes is the production of relatively large amounts of sodium hydrogensulfate contaminated with residual dialkyl sulfate.

4.4. From Alcohols and Sulfuryl Chloride or Thionyl Chloride

If alcohols and sulfuryl chloride react in a molar ratio of 1 : 1, alkyl chlorosulfates are produced.

$$\mathrm{ROH + Cl{-}SO_2{-}Cl \longrightarrow RO{-}SO_2{-}Cl + HCl} \qquad (1)$$

Alcohols and thionyl chloride react readily to produce dialkyl sulfites [22].

$$\mathrm{2\,ROH + Cl{-}SO{-}Cl \longrightarrow RO{-}SO{-}OR + 2\,HCl} \qquad (2)$$

Dialkyl sulfites prepared according to Equation (2) react directly with the alkyl chlorosulfates to form dialkyl sulfates. Prior purification is unnecessary.

$$\mathrm{RO{-}SO_2{-}Cl + RO{-}SO{-}OR \longrightarrow RO{-}SO_2{-}OR + RO{-}SO{-}Cl} \qquad (3)$$

Reaction (3) can be carried out at 130 °C or, if zinc chloride is used as catalyst, at 90 °C; the reaction time is ca. 6 h [23]. Under these conditions, an exchange of alkyl groups takes place

(see Chap. 3); therefore, only symmetrical dialkyl sulfates can be produced.

Another process operates at 45 °C, with a reaction time of 2 h [24]. This enables a reaction between sulfites and chlorosulfates with different alkyl groups; no exchange of alkyl groups occurs. However, the alkyl chlorosulfates, especially those with long-chain alkyl groups, must be stabilized, e.g., by an alkyl chlorosulfite. Chlorosulfites are always present when the dialkyl sulfite rather than the alcohol is used in reaction (1) [25]:

$$\mathrm{RO{-}SO{-}OR + Cl{-}SO_2{-}Cl \longrightarrow RO{-}SO{-}Cl + RO{-}SO_2{-}Cl} \quad (4)$$

Despite an increased amount of valueless byproduct (RO−SO−Cl), this variant of Equation (1) is often preferred in the process operating at higher temperatures because of its smoother progress.

To produce a symmetrical dialkyl sulfate, only one sulfite is needed. If an unsymmetrical dialkyl sulfate is desired, however, the reaction of two different alcohols according to Equation (2) is necessary.

At the relatively high temperatures required in the older process, alkyl chlorosulfites decompose to sulfur dioxide and alkyl chloride. In the low-temperature process subsequent decomposition in aqueous alkali is necessary.

In the production of unsymmetrical dialkyl sulfates, yields are considerably higher if the longer-chain sulfite is used in Equation (4) and the sulfite with the smaller alkyl group in Equation (3). The overall reaction is as follows:

$$\mathrm{4\,ROH + 2\,SOCl_2 + SO_2Cl_2 \longrightarrow R_2SO_4 + 4\,HCl + 2\,RCl + 2\,SO_2} \quad (5)$$

This process is especially suitable for the production of higher, unsymmetrical dialkyl sulfates.

For further production methods, see [26], [27], [28].

4.5. From Alcohols and Sulfuric Acid

Reaction of alcohols with sulfuric acid can be used to produce alkylsulfuric acids.

$$\mathrm{ROH + H_2SO_4 \rightleftharpoons ROSO_3H + H_2O}$$

With excess sulfuric acid, the equilibrium can be shifted to the right. The alkylsulfuric acid may be isolated in the form of its alkali-metal salt, after neutralization in the cold and precipitation of the sulfate anion as barium sulfate. At higher temperature (120 – 140 °C), dialkyl ethers are produced. Use of oleum or sulfur trioxide leads to sulfonation. Thus ethionic acid [*461-42-7*], $\mathrm{HO_3S{-}CH_2CH_2{-}O{-}SO_3H}$, is produced readily from ethanol and sulfur trioxide [19].

5. Quality Specifications and Analysis

Commercial dimethyl sulfate (99.8 – 99.9 wt %) contains 0.1 – 0.2 % acid, calculated as sulfuric acid, and dissolved dimethyl ether in concentrations of a few parts per million. Other impurities are sulfuric acid and alkanesulfonic acids (see Section 4.1). Although the following specifications and analytical procedures pertain to dimethyl sulfate they are, in principle, also applicable to its nearest homologues.

Assay. (1) A sample is boiled for at least 30 min under reflux with dilute hydrochloric acid. The hydrochloric acid is then removed completely by evaporation with repeated addition of water. The sulfuric acid left behind is taken up in water and titrated [29] .

(2) A sample is stirred for 12 h at 20 °C in water to which an approximately equivalent amount of sodium hydroxide has been added. The excess hydroxide is then back-titrated. Because hydrolysis stops at the monomethyl sulfate, free sulfate ions can be determined with barium chloride in the cold solution after a small amount of hydrochloric acid has been added.

In both methods, the free acid must be determined separately and subtracted from the result.

Another method is based on the formation of methyl iodide from dimethyl sulfate and potassium iodide.

$$\mathrm{(CH_3)_2SO_4 + KI \longrightarrow CH_3SO_4^- + K^+ + CH_3I}$$

An aqueous methanol solution of a measured amount of potassium iodide is added to the sample with mild heating. Excess potassium iodide is titrated according to the Volhard method or potentiometrically with silver nitrate [29].

Determination of the Free Acid. The sample is suspended in ice – water or extracted by shaking with ice – water. The dissolved acid is then titrated with sodium hydroxide, by using methyl orange as indicator. Rapid assay at low temperature is essential to prevent significant formation of acids by hydrolysis.

The free acid can also be titrated with sodium acetate in glacial acetic acid, by using crystal violet as indicator. This accounts only for the first dissociation step of any sulfuric acid present [29].

The alkylsulfuric acid and sulfuric acid contents of dimethyl sulfate can be determined separately by potentiometric titration (glass electrode) with tributylethylammonium hydroxide [*16208-32-5*] in a water-free medium. This procedure is also suitable for diethyl sulfate [30].

Determination of Dimethyl Ether. The liquid sample is dripped by means of a syringe onto diatomaceous earth; a given amount of air is then passed over the absorbed liquid and collected in an evacuated bottle. The ether content of the air is determined in the usual manner by gas chromatography [29].

Determination of Dimethyl Sulfate Vapor in Air. Small amounts of dimethyl sulfate in air can be determined by using special test tubes in which concentrations can be read directly from color changes (Manufacturer: Drägerwerk AG, Lübeck, Germany). Reliable detection of levels as low as 0.005 ppm can be achieved.

In addition, test kits are available such as the MSA Universal Tester and the Dräger Multigas Detector and these can measure dimethyl sulfate down, to 0.005 ppm (Dräger) and 1.0 ppm (MSA) by volume.

One process involves the following steps (sample volume 500 L): (1) absorption from air onto silica gel; (2) elution with acetone; (3) reaction with nitrophenol by reaction of dimethyl sulfate or with sodium *p*-nitrophenoxide (DuPont Analytical Methods) [31]; (4) separation of the methylation product by thin-layer chromatography; (5) staining of the elution zone by reduction, diazotization, and coupling; and (6) comparison of the color intensity with a standard [32]. In one variant of this process, nitroanisole is determined by gas chromatography after step 3.

Continuous monitoring of rooms in which dimethyl sulfate is processed can be achieved with flame photometry using a sulfur detector (Messer Griesheim AG, Düsseldorf). If no other sulfur compounds are present (particularly SO_2 and CS_2), dimethyl sulfate levels from 0 to 0.5 ppm can be indicated. The last two methods are recognized by the chemical industry trade association in Germany [33].

6. Storage, Transportation, and Handling

Employees should be thoroughly informed and trained on the precautions that must be followed in the safe handling of dimethyl sulfate (DMS) and diethyl sulfate (DES). The area where DMS and DES are handled must be well ventilated and clearly marked to prevent entry by nonoperating personnel. The proper personal protective equipment must be worn to protect from any exposure.

It is important to refer to the manufacturers (for example see [31]) guidelines for the storage, transportation, and handling of DMS and DES. Since shipping regulations change over time, the user should refer to current applicable regulations such as those issued by the proper governmental authorities (for example, in the U.S. they are the DOT, EPA, OSHA, and The U.S. Food and Drug Administration) for additional information.

As a general guideline the physical and chemical properties of DMS and DES are shown in Table 3.

The presence of dimethyl sulfate can be detected by using the color reaction with 4-(4-nitrobenzyl)pyridine [*1083-48-3*] [35]. The sensitivity is about 20 mg/L. This method is also suitable for spot analysis.

First aid treatment after accidents with liquid or gaseous dimethyl sulfate involves thorough flushing of affected skin areas with 5 % ammonia solution. All clothing soiled with dimethyl sulfate should be removed immediately and decontaminated. A doctor must be consulted; symptoms may develop after a latency period of several hours (see Chap. 10).

Absorption by diatomite is the best way to clean up spilled dimethyl sulfate; 1 kg of diatomite binds 5 – 6 kg of dimethyl sulfate to form a doughlike mass.

A 5–10 % aqueous ammonia solution is commonly used to break down dimethyl sulfate. The resulting compounds are methylamine, dimethylamine, and methyl sulfate anion. Without mixing and at ambient temperature, the dimethyl sulfate tends to settle (ϱ 1.329 g/cm^3) and several days may be necessary for the reaction to be complete. However, with effective stirring, breakdown is complete in ca. 3 min. Methylamine and dimethylamine have very unpleasant, persistent odors. The odor nuisance can be avoided by using an approximately 2 M aqueous solution of hexamethylenetetramine [*100-97-0*] instead of ammonia. In this case, a nonvolatile methyl sulfate salt is formed [36]. If hexamethylenetetramine is dissolved in a mixture of two parts water and one part diethylene glycol monobutyl ether, a homogeneous phase is obtained with dimethyl sulfate, and stirring is unnecessary. Because the breakdown of dimethyl sulfate with ammonia or hexamethylenetetramine is always an exothermic reaction, the volume of breakdown agent should be five times that of dimethyl sulfate. Solid hexamethylenetetramine reacts explosively with dimethyl sulfate. Dry alkali such as soda or lime is unsuitable as a breakdown agent.

Table 3. Physical and chemical properties of dimethyl sulfate and diethyl sulfate

	Dimethyl sulfate	Diethyl sulfate
Solubility in water, g/100 g	2.8 (18 °C) (reacts)	0.7 (reacts)
Boiling point, °C	188 (decomp.)	208 (decomp.)
Density of vapor (air = 1)	4.35	5.31
Flash point, °C (Closed Cup)	83	104
Ignition temperature (DIN 51 794), °C	470	395
Temperature class (VDE 0165)	T 1	T 2
Explosive limits, vol %		
Lower	3.6	1.8
Upper	23.2	12.2
Heat of combustion at constant pressure [25 °C; CO_2, H_2O, H_2SO_4 (aqueous)], J/g	11 970	18 110
Heat of vaporization at 25 °C, J/g [10]	385	368
Heat of formation at 25 °C (liquid), kJ/mol	736	812

The higher homologues of dimethyl sulfate behave similarly, but longer reaction times are required.

If dimethyl sulfate gets into insulation, complete dismantling and destruction of the porous materials are necessary.

Large quantities of water and dimethyl sulfate must not be allowed to come into contact in an uncontrolled manner: the acid and heat produced during hydrolysis may result in a continuously increasing speed of reaction. In addition, the acid attacks iron containers, and a substantial buildup of hydrogen pressure may result.

Technical-grade dimethyl sulfate contains small amounts of dimethyl ether, a flammable gas, which can collect in the air space in containers during prolonged storage. Some dimethyl ether may also be generated during reaction in alkaline solution. In this case, it may be found in either the waste gas or the final product; a considerable amount of dimethyl ether can accumulate in the solvent.

Further information on safety precautions can be found in [31], [37–39].

7. Environmental Protection

Buildings in which large amounts of dimethyl sulfate are stored or handled must not have drainage that leads directly into the public sewer system; traps must be installed to test and, if necessary, monitor effluents. Disposal of waste liquid streams containing dialkyl sulfates must follow the regulations in force on the local, state, and national levels.

In most alkylations with dialkyl sulfates in aqueous alkaline media, the effluent contains half of the organic component of the dialkyl sulfate in the form of salts of alkylsulfuric acid. These salts are biodegradable. Alternatively, if permitted, they can be hydrolyzed completely under pressure and at higher temperature; the alcohol produced is recovered by distillation. Acid hydrolysis at low temperature is also possible, but subsequent neutralization is required.

Activated carbon may be used to absorb dimethyl sulfate vapors in waste gas. The carbon can be regenerated by treatment with dilute ammonia solution [40] or with water for several hours. Drying is not necessary.

8. Uses

8.1. Alkylation

The most important use of dialkyl sulfates is in alkylation. In this application, dialkyl sulfates must compete with alkyl halides, which are also important alkylating agents (→ Acylation and Alkylation). Halides, especially chlorides, are considerably cheaper; in addition, chlorides result in a lower salt load in the effluent. However, dimethyl and diethyl sulfate can be processed at atmospheric pressure because of their higher boiling points, and their high reactivity enables conversion to occur at lower temperatures. Dimethyl sulfate is by far the most important dialkyl sulfate because it is cheaper and more reactive than its homologues. Diethyl sulfate also has commercial significance, whereas higher homologues or unsymmetrical and cyclic dialkyl sulfates are used only in special applications.

Alkylation is usually carried out in stirred vessels. The alkylating agent is added slowly to an aqueous alkaline solution or suspension of the compound to be alkylated. Where large volumes are concerned, gradual addition of the alkali during the reaction is preferred, to maintain a certain pH. In the alkaline range, steel equipment may be used. Stainless steel or enamel is recommended for weakly acidic media or for sensitive products (e.g., quaternized dyes).

If the reaction does not proceed in an aqueous alkaline medium, treatment of the dry alkali-metal salt with dialkyl sulfate, in the presence of an inert solvent if necessary, is often successful. Occasionally, the pure substance is fed into dialkyl sulfate above 100 °C. However, increased side reactions (e.g., sulfonations) must be expected under these conditions.

Etherification. The classic use of dimethyl sulfate is to etherize an aromatic hydroxyl group in aqueous alkaline solution:

Dimethyl sulfate is added at 10 °C over 1 h, and the mixture is heated at 80 °C for 30 min; the yield is 90 % [41]. This reaction requires the presence of phenolate ions and therefore proceeds only at sufficiently high pH. The second methyl group of dimethyl sulfate may also be utilized if the mixture is refluxed for 15 h, but this is accompanied by reduced yield.

In strongly alkaline solution, the hydroxyl group reacts more rapidly than the carboxyl group:

Small amounts of trimethoxybenzoic acid ester formed as byproduct are hydrolyzed by heating at 100 °C for 2 h.

Near neutral pH, however, the carboxyl group is alkylated more rapidly than the phenolic hydroxyl group. An example is the production of methyl salicylate [43]:

Because of steric hindrance, the two *ortho* hydroxyl groups of dimethyl dihydroxyterephthalate [*610-92-4*] can be etherized only under special conditions:

Sodium methoxide is used as the base, and the alkylation is carried out in dimethylformamide

(DMF) at 65 °C. The reaction is completed by heating rapidly to 100 °C. The product shows a strong bluish fluorescence and can be used as a brightener for polyester fibers [44].

Steric hindrance also affects alkylation of 2,4,6-trihydroxybenzoic acid [*83-30-7*]. Both hydroxyl groups in the *ortho* position remain free although esterification occurs [45]:

Selective methylation of one hydroxyl group is also possible. For example, hydroquinone monomethyl ether is obtained in 84 % yield if alkylation is carried out in a relatively large amount of an inert solvent (benzene), which extracts the monomethyl ether from the reaction mixture [46]:

The aliphatic hydroxyl group can also be alkylated with dialkyl sulfates in the usual way if it is sufficiently activated by neighboring groups:

Dimethyl sulfate is partially recovered, and the low temperature reduces losses from hydrolysis [48]. In a strongly acidic medium, the non-activated aliphatic hydroxyl group is selectively methylated before the amino group, although the yield is low (30 %) [49]:

An unexpected byproduct of the methylation of phenol and other hydroxyaromatic compounds by dimethyl sulfate in the presence of tetrahydrofuran (THF) and potassium carbonate is the 4-methoxybutyl ether. In some cases, this is obtained in considerable quantities in addition to the normal methyl ether [50]:

Esterification. Fatty acid ethyl esters, which can be used as plasticizers, are produced according to the following reaction [47]:

$$2\,R{-}COONa + (C_2H_5)_2SO_4 \longrightarrow 2\,R{-}COOC_2H_5 + Na_2SO_4$$

Both ethyl groups of the sulfate are utilized and therefore prolonged heating at 150 °C is necessary. The yield drops sharply outside the pH range of 7.5 – 8.5. Diethyl sulfate should be added at temperatures between 70 and 90 °C, never above 95 °C. If calcium salts are used instead of sodium salts, the second ethyl group does not react, because calcium bis(ethyl sulfate) [*926-03-4*] is unstable above 100 °C. Monomers of acrylic resins (raw materials for varnishes) and acrylic glass can also be produced by esterification with diethyl sulfate. The reaction is of commercial interest because diethyl sulfate is continually regenerated by feeding in ethylene. The process is also applicable to lower saturated fatty acids [47].

N-Alkylation. Ammonia and aliphatic or aromatic amines are alkylated readily by lower dialkyl sulfates. The reaction may progress to the tetraalkylammonium ion (quaternization). Quaternization leads to the formation of an organic cation; i.e., a positively charged, strongly hydrophilic center is created within the molecule. The corresponding anion is usually the alkyl sulfate ion (RSO_4^-) or the sulfate ion (SO_4^{2-}) produced during the reaction, although in some cases the cation can be associated with other suitable anions.

Quaternization can increase the water solubility of a drug or the affinity of a dye molecule for a negatively charged fiber. Numerous organic ammonium derivatives are used as raw materials for detergents, textile auxiliaries, and antistatic agents.

Most quaternizations can also be achieved with methyl chloride. However, methylsulfuric acid salts (methosulfates) often yield preparations with better consistency and greater solubility in water than the chlorides. The sodium methyl sulfate produced during methylation can often be tolerated in the product and does not have to be removed. For plastics additives that are put into the melt, the greater heat stability of methyl sulfates is a desirable property. In addition, many products must be free of chloride ions to prevent corrosion during subsequent processing.

Quaternization is feasible with aromatic, aliphatic, and heterocyclic compounds [51]. For example, pyridine reacts with dimethyl sulfate in the absence of a solvent to form methylpyridinium methyl sulfate [48]. Treatment of nitro-2-hydroxyquinolines with dimethyl sulfate also yields the quaternary base (**4**). If the nitro group is in the 8-position, i.e., adjacent to the nitrogen, steric hindrance inhibits *N*-alkylation, and 2-methoxyquinoline is the main product (**5**) [52].

4

5

Alkylation of the dry potassium salt of carbazole in chlorobenzene at 100 °C gives *N*-ethylcarbazole [*86-28-2*] in 99 % yield; both alkyl groups react [53]:

Also the alkylation of *p*-toluidine with two equivalents of dimethyl sulfate in the presence of sodium bicarbonate leads to *N,N*-dimethyl-*p*-toluidine [54].

Indirect methods must often be used to obtain the desired product. Thus, *N*-methylbutylamine [*110-68-9*] is produced from butylamine [*109-73-9*] in 49 % yield by the following reaction sequence [55]:

To prevent more than one methyl group from attaching to the nitrogen atom, the first step is formation of the Schiff base with benzaldehyde. After methylation, the Schiff base is then hydrolyzed. Reaction of urea with dialkyl sulfates usually gives the alkyl compound of the enol form, −C(OR)=NH. The cyclic amide caprolactam behaves similarly [56]:

However, some urea derivatives react in the keto form, $-CO-NH_2$, which yields *N*-alkylated compounds. An example is the final step in the synthesis of a chlorinated *N*-phenylurea [57]:

The hydroxyl group and the amino group are methylated in a single operation. The resulting *N*-dichlorophenyl-*N′*-methyl-*N′*-methoxyurea and compounds of similar structure are used in large quantities as herbicides.

Hydrazine is also methylated readily. An indirect pathway via a diacyl compound is pre-

ferred for the synthesis of symmetrical dimethylhydrazine [*540-73-8*] [58]:

C-Alkylation. Compounds that can react as either ketones or enols (ambident nucleophiles, e.g., acetoacetic ester) may undergo *C*-alkylation (−CO−CHR−) in addition to *O*-alkylation (−C(OR)=CH−). Aromatic compounds with several hydroxyl groups in the meta position, e.g., resorcinol [*108-46-3*] and phloroglucinol [*6099-90-7*], react accordingly. In addition to ethers, small amounts of compounds in which the alkyl group is located at the aromatic nucleus are formed [59].

S-Alkylation. Phenols carrying a thiocyano group react with dimethyl sulfate in aqueous alkali to form thioethers.

The hydroxyl group remains unaltered and the cyano group is split off [60].

In addition, mercaptan salts are rapidly methylated with dimethyl sulfate. The thioethers can further react to form the water soluble sulfonium salts [61].

Alkylation of Inorganic Salts. Water-soluble metal halides can be converted to alkyl halides by reaction with dialkyl sulfates. A well-known example is the production of methyl iodide from potassium iodide [62]. Other salts can be alkylated similarly, e.g., sodium sulfide to diethyl sulfide or sodium sulfite to methanesulfonic acid [64] and sodium disulfide to dimethyl disulfide [63]. Di-*tert*-butyl peroxide, which is used as a polymerization catalyst, is produced continuously in a cooled, vertical reaction tube from hydroperoxide and a mixture of *tert*-butyl hydrogen sulfate and di-*tert*-butyl sulfate [65].

Sulfonation. At high temperature, reaction with dialkyl sulfates may lead to sulfonation. This results from the equilibrium between dialkyl sulfates, on the one hand, and sulfur trioxide and the corresponding ether, on the other (see Section 4.1).

$$R_2SO_4 \rightleftharpoons SO_3 + R_2O$$

For example, if diphenyl ether or diphenylmethylamine is heated with diethyl sulfate for several hours at 150 °C, phenylsulfonic acids are produced [66].

8.2. Other Uses

The lower dialkyl sulfates are used occasionally as a source of acidifiers in thermosetting resins, as stabilizers for various chemicals, and as selective solvents for aromatic compounds in petroleum fractions.

An interesting application in preparative chemistry is the protection of the hydroxyl group against oxidation by esterification with sulfuric acid. For example, *tert*-butyl sulfate is oxidized with nitrogen dioxide at about 15 °C, leading to the conversion of a methyl group into a carboxyl group. After hydrolysis, a sulfuric acid solution of α-hydroxyisobutanoic acid [*594-61-6*] is obtained [67].

Dimethyl sulfate can also act as a catalyst in certain reactions. For example, when it is mixed with titanium or vanadium halides it acts to catalyze the polymerization of olefins at low temperatures [68].

9. Economic Aspects

The production of dimethyl sulfate in Western Europe totals approximately 50 000 t/a [69]. There are no production figures reported for the United States. Diethyl sulfate production is estimated to be much lower. The higher dialkyl sulfates are not commercially available on a large scale, although small quantities are available for speciality synthesis.

The following companies produce dimethyl sulfate: Celanese and DMS Chemie Produktionsgesellschaft (Germany); Rhodia (France); Säurefabrik Schweizerhalle (Switzerland); DuPont, and Schweizerhall (United States); Lei Chang Yung Chemical Industry, Heng Chemical and Consul Chim (Taiwan); Hodogaya Chem., and Tsujimoto Kagaku Kogyo (Japan); and many producers in China, and

India [69]. Other countries which are listed as producing DMS are Mexico and the United Kingdom.

Diethyl sulfate is produced by Union Carbide (soon to be merged into Dow Chemical) in the United States. It is also produced by Nisso Maruzen (Japan); Dharamsi Morarji Chem and Industrial Solvents & Chemical (India).

The selling price of dimethyl sulfate in October 1999 was listed as $ 1.23/kg and for diethyl sulfate as $ 2.36/kg [70].

10. Toxicology and Occupational Health

10.1. Dimethyl Sulfate

Acute Toxicity. Inhalatory LC_{50} values in laboratory rodents (30 – 60 min) are between 30 and 75 ppm in the inhaled air [71], [72]. The 4-h LC_{50} is 45 mg/m^3 [73]. When humans are exposed to low concentrations, conjunctivitis with photophobia and irritation of the mucosal membranes of the upper respiratory tract result. Severe intoxication is characterized first by minor symptoms of local irritation of eyes, nose, throat, trachea, and bronchi; after a latency period of several hours lung edema may develop. If the lung edema is not lethal, bronchopneumonia and lung emphysema are typical secondary symptoms [74–85]. The oral LD_{50} values are between 205 and 404 mg/kg in laboratory animals [73]. In addition, dimethyl sulfate is corrosive to the eyes and skin [86].

Chronic Toxicity, Carcinogenicity, and Mutagenicity. Inhalation by mice, rats, and hamsters of 0.5 ppm over a period of 15 months caused severe inflammation in the mucosa of the nose and in the lungs as well as increased mortality [87]. Long-term inhalation of 0.5 ppm of dimethyl sulfate induced malignant tumors in the nose and the sinusoidal membranes in rats, mice, and hamsters [88], [89]. Compared to other compounds with alkylating properties, dimethyl sulfate has a rather weak methylating activity, probably because it is quickly hydrolyzed after contact with wet mucosal membranes. Therefore, it induces local tumors but no tumors remote of the site of the primary contact. Dimethyl sulfate is a directly acting mutagen [90–94]. It methylates DNA in rat liver, lung, and intestine [95]. For additional references, see [86], [96–98].

10.2. Diethyl Sulfate

In animal experiments, diethyl sulfate is a more potent alkylating agent than dimethyl sulfate.

Acute Toxicity. The acute toxicity of diethyl sulfate is lower than that of dimethyl sulfate: LC_{50} (rat, 4 h) > 250 ppm [99], LD_{50} (rat, oral) 350 – 1000 mg/kg [99]. Also the LD_{50} (rabbit, dermal) is reported to be 600 mg/kg [100]. The corrosive effect is weaker than that of dimethyl sulfate because hydrolysis occurs slower, but solutions containing 40 % burn the eyes of rabbits [106]. Lethal intoxications are characterized by lung edema occurring after a latency period of 10 – 20 h. Diethyl sulfate appears to be severely irritating or corrosive to the eyes and skin.

Chronic Toxicity and Carcinogenicity. After chronic oral administration of diethyl sulfate to rats (25 and 50 mg/kg in weekly intervals) benign tumors of the forestomach and one squamous cell carcinoma, but no systemic tumors, occurred. This probably results from rapid hydrolysis of diethyl sulfate in the stomach [101]. Subcutaneous administration also produced only local tumors at the site of injection [74], [107], [108]. In offsprings of dams who had been treated with diethyl sulfate during pregnancy, tumors of the central nervous system and multiple mammary cancer occurred [101]. Some additional references are worth consulting [102–105].

Mutagenicity. Diethyl sulfate is mutagenic in bacteriophages [109], in *E. coli* [110], [111], in *Drosophila* [112], [113], and in the dominant lethal assay in mice [114]. Cytogenetic studies in mice induced increased frequencies of aneuploidy in bone marrow but no structural chromosomal aberrations [115]. Diethyl sulfate is also positive in the point-mutation assay in Chinese hamster ovary cells [108].

1. Introduction

A diazo compound is an aliphatic, aromatic, or heterocyclic compound in which an $-N_2$ group is attached to a carbon atom. This group can be present as such (diazo compounds in the narrowest sense), it can carry a positive charge (diazonium salts), or the nitrogen atom in the β-position can carry a substituent (diazo compounds in the general sense). Compounds containing the $RN_2^+X^-$ group are named by adding the suffix "diazonium" to the name of the parent compound RX, followed by the name of X^- (e.g., benzenediazonium chloride), whereas compounds having the N_2 group in the neutral form attached to a carbon atom are named by adding the prefix "diazo" to the name of the parent compound (e.g., diazomethane). In azo compounds, the N_2 group is substituted on both sides by carbon atoms. A overview on nomenclature is given in [6].

Diazo- and diazonium compounds are reactive molecules. They readily take part in a variety of reactions, which gives them their value to the chemical industry. The reactions, which normally take place rapidly and smoothly, lead to a number of important intermediates and end products. Their main importance, however, is as a first step in the preparation of azo pigments and azo dyes (→ Azo Dyes)

2. Aliphatic Diazo Compounds

Aliphatic diazo compounds have an open chain structure, which may be represented by the following mesomeric formulas:

With few exceptions, aliphatic diazo compounds lack the ability for azo coupling, and as a result they are of less industrial importance. While handling diazomethane or other diazo compounds appropriate care has to be applied. Nevertheless, due to the great synthetic potential in organic chemistry, quite a number of diazo compounds and precursors are commercially available [7]. The simplest diazo compound is diazomethane [*334-88-3*], CH_2N_2, *bp* −23 °C, *fp* −145 °C, a yellow gas, which is explosive both as gas and in concentrated solution. It is prepared by reacting an alkali metal hydroxide with *N*-nitroso-*N*-methylurea [*684-93-5*] or *N*-nitroso-*N*-methyl-4-toluenesulfonamide [*80-11-5*], e.g., in diethyl ether. *N*-Methyl-*N*-nitro-*N*-nitrosoguanidine is also used in the synthesis of diazomethane (for

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a08_505

details, see [7] and references cited therein). Solutions of diazomethane decompose slowly, even at room temperature, liberating nitrogen.

Diazomethane has been used in the esterification of unstable carboxylic acids and generally as a methylating agent. Because of its toxicity (see Chap. 7) and explosive properties, however, its industrial use is rather limited.

Many synthetic methods for the preparation of diazo compounds and diazocarbonyl compounds are available [6–9]. A covenient route is the diazo transfer reaction [8], in which the N_2 group is transferred from an N_2 donor (a sulfonyl azide) to a suitable acceptor molecule. For example, tosyl azide TsN_3 reacts with *tert*-butyl acetoacetate to give the corresponding*tert*-butyl α-diazoacetoacetate.

In the Arndt–Eistert synthesis, diazomethane is used to convert an acid chloride into a carboxylic acid with an additional carbon atom ($RCOCl \rightarrow RCH_2COOH$). The reaction proceeds via Wolff rearangement of the initially formed diazoketone on treatment with water and silver ion catalysis or photolysis. With alcohols $R'OH$ or ammonia instead of water the esters RCH_2COOR' or the amide are obtained, respectively [6].

Ring contraction occurs during Wolff rearrangement of cyclic 2-diazoketones, whereas ring expansion of a cyclic ketone to the next higher homologue can be achieved by reaction with diazomethane (e.g., cyclohexanone to cycloheptanone). A prominent example for industrial application of the Wolff rearrangement is the diazonaphthoquinone(DNQ)/novolak system used in photoresists [14–17]. In the early 1940s, Süs observed inhibition of novolak dissolution by a diazonaphthoquinone sulfonate. However, on exposure of these coatings to sunlight, they dissolved faster than the pure novolak. Süs realized the potential of his observation and the first Kalle positive-tone printing plate consisting of a DNQ/novolak system on aluminum was introduced in 1950 (Ozatec). The novolak/DNQ systems have been optimized to maximize this effect. In modern resists, dissolution rate between exposed and unexposed resist regions differ by over three orders of magnitude. DNQ loading is ca. 5 – 10 %. Diazonaphthoquinone (DNQ) is photolytically converted into a 3-carboxyindene, which unlike the diazonaphthoquinone is more soluble in aqueous bases.

Substituted DNQs used in photoresists include 1,2-diazonaphthoquinone-4- or 5-sulfonate esters [16], [17] and 7-hydroxy-1,2-naphthoquinone-2-diazide-4-sulfonic acid. Other aliphatic diazo reagents used in organic synthesis are diphenyldiazomethane [*883-40-9*] and ethyl diazoacetate [*623-73-4*].

Alkyldiazoacetates react with a hydrazone aldehyde in the presence of Lewis acids to form hydrazone β-ketoesters, which are precursors for pyridazinones [18]. Certain pyridazinones are plant-growth regulators.

A great number of diazo- and diazo carbonyl compounds are accessible. Synthesis and versatility in organic transformations are covered by comprehensive reviews [6–9].

3. Aromatic Diazo Compounds

The most important aromatic diazonium compounds are the diazonium salts (Section 4.1). Other diazo compounds are:

- Aryldiazotates
- Aryldiazoethers
- Aryldiazoesters
- Aryldiazosulfides
- Aryldiazosulfones
- Aryldiazosulfonates
- Aryldiazophosphorous esters
- Aryldiazoamino compounds

Since the above-mentioned compounds show typical coupling reactions they can be considered as masked diazonium compounds.

3.1. Diazonium Salts

The diazonium cation is a mesomeric system that can be represented by the following mesomeric structures:

Conjugation with the π electrons of the aromatic system renders aryldiazonium ions much more stable than alkyldiazonium ions. Aromatic diazonium salts can be isolated as moderately stable compounds.

3.1.1. Properties

Diazonium salts are known with many inorganic and organic anions. Salts of strong acids are completely dissociated in aqueous solution, and such solutions are neutral, because aryldiazonium ions show little tendency to hydrolyze. A large number of salts with complex anions are known [1], [2], [19]. Salts of industrial relevance contain anions such as chloride, hydrogensulfate, tetrafluoroborate, tetrachlorozincate, and naphthalene-1,5-disulfonate, the solubilities of which decrease in that order. Diazonium compounds formed from aromatic sulfonic or carboxylic acids, being zwitterions, are sparingly soluble unless additional solubilizing groups are present.

Many diazonium salts are explosive when dry, some even when moist, an extreme example being diazotized aminotetrazole, which can explode even in aqueous suspension. Explosion can be initiated by heat, friction, or impact. Extremely unstable salts occasionally explode without any apparent external cause. Nitrates, perchlorates, and iodides must be handled with great care. The risk of explosion decreases in the order iodide, bromide, and chloride; and in the order tetrachlorozincate, hydrogensulfate, tetrafluoroborate, and naphthalene-1,5-disulfonate; the latter group of anions is preferred for safety reasons. Nitro groups on the aromatic nucleus increase the risk of explosion, while alkylamino and especially arylamino groups reduce it. The pressure increase in the exothermic decomposition was investigated [20], and the explosion properties were studied calorimetrically [21].

Gradual decomposition of diazonium salts occurs at or just above room temperature, and nitrogen is cleaved from the molecular ion [22]. For many industrial diazonium salts, the extent of decomposition is less than 1 % after one month at 40 °C.

Diazonium salt solutions are also not stable indefinitely, especially at elevated temperatures. Decomposition in dilute mineral acid is a first-order reaction. The rate of decomposition, which is largely independent of the anion and almost entirely determined by the cation, increases about fourfold for a 10 °C rise in temperature [23]. Solutions of diazonium naphthalenesulfonates are exceptional because of π-complex formation, which stabilizes the cations [4]. Figure 1 shows the rate of decomposition of some diazonium chloride solutions at various temperatures.

For mineral acid concentrations between 0.1 and 10 wt %, the rate of decomposition is practically constant. Solutions in more highly concentrated sulfuric acid are usually more stable: the rate of decomposition of 2,4-dinitrophenyldiazonium ion in 85 wt % sulfuric acid is ca. 60 times less than in 63 wt % sulfuric acid. The system H_2O/H_2SO_4 is very complex [24] and the effect can be understood by the absence of reactive particles and the decreasing activity of water and sulfate ions. Many diazonium salts of heterocyclic amines, e.g., of 2-aminobenzothiazole, are stable only in concentrated sulfuric acid; dilution with water leads to rapid decomposition. Increasing pH also accelerates decomposition. Although a pH > 3 may be suitable for azo coupling, the rate of decomposition can exceed that in mineral acids by several orders of magnitude. The outcome of any such experiment is controlled kinetically, for instance, by very rapid coupling. The maximum rate of decomposition occurs at pH values at which concentrations of diazonium ion and diazotate ion are equal [25].

3.1.2. Diazotization

Although continuous diazotization processes are known [26–31], crystalline diazonium salts are

Figure 1. Decomposition half-life of mineral acid solutions of diazonium salts as functions of temperature (partly extrapolated) Diazonium chloride solutions (ca. 0.1 mol/L, pH ca. 1.5) prepared from: 1) 5-Amino-1,4-dimethylbenzene; 2) 3-Aminophenol; 3) 3-Ethylaniline; 4) 2-Aminotoluene; 5) 3-Aminotoluene; 6) 3-Aminoanisole; 7) Aniline; 8) 4-Amino-1,3-dimethylbenzene; 9) 4-Chloro-2-aminotoluene; 10) 2-Aminonaphthalene; 11) 3-Aminobenzenesulfonic acid; 12) 6-Chloro-2-aminotoluene; 13) 4-Aminotoluene; 14) 2-Aminobenzenesulfonic acid; 15) 4-Aminobenzenesulfonic acid; 16) 4-Aminoazobenzene; 17) 3-Chloroaniline; 18) 5-Nitro-2-aminotoluene; 19) 4-Nitro-2-aminotoluene; 20) 2-Aminophenol; 21) 4-Nitroaniline; 22) 4-Chloroaniline; 23) 3-Nitroaniline; 24) 4-Aminophenol; 25) 2-Nitroaniline; 26) 4-Aminoanisole; 27) 2-Chloroaniline; 28) 1,4-Diaminobenzene (only one amine group diazotized); 29) 2,4-Dichloroaniline

still made by the batch method without exception. Apart from the well-known problems associated with continuous operation of a multiphase process, the low production volumes could well be the reason for batch operation. For the details of specific industrial diazotization procedures, see [32–34]. Whenever suitable, *direct diazotization* in dilute hydrochloric acid with sodium nitrite is the process of choice. The amine should either be completely dissolved in the liquid phase or prepared as fine, lump-free suspension of the free amine or the amine hydrochloride. Amines that are liquid at room temperature or that melt below ca. 70 °C are slowly added as liquids with vigorous agitation to dilute hydrochloric acid at temperatures about equal to or higher than the melting point of the amine. For each mole of amine, 2.3 – 3.0 mol of hydrochloric acid and 180 – 500 mL of water are required, depending on the molecular mass of the amine. To prevent lump formation, only the amount of hydrochloric acid necessary to form the hydrochloride (ca. 1.2 mol) is used; the remainder required for diazotization (1.1 – 1.8 mol) is added at a later stage.

Amines melting above 80 °C are slurried in water at ambient temperature to prepare a fine suspension before mineral acid is added. Hard agglomerates are broken down by stirring or with high-speed rotor – stator homogenizers or auxiliary disk mills. The hydrochloric acid is then added slowly to form the hydrochloride.

Diazotization is usually carried out between 0 and 15 °C with external cooling to avoid side reactions and decomposition. When the starting temperature has been established, a concentrated solution of sodium nitrite is added as quickly as possible without the evolution of nitrous gases (NO_x). The rate of nitrite addition is usually adjusted to match the rate of consumption, monitored by spot testing with 3,6-diamino-9*H*-thioxanthene-10,10-dioxide [*10215-25-5*] ("sulfone reagent") or redox measurement. The heat of reaction, ca. 100 kJ/mol, must be removed continuously, which frequently imposes a limit on the speed of the process.

Nitrite depletion of the reaction mixture must be avoided to suppress side products. Certain amines require quick addition of all the nitrite, in practice within 1 – 2 min, 4-nitroaniline being a well-known example. In such cases, the heat of reaction cannot be removed fast enough by external cooling; hence, either the starting temperature must be very low (−10 to −15 °C) and/or ice must be added for internal cooling. In the diazotization of aminoazo compounds or aminonaphtholsulfonic acids and in some continuous diazotization processes, higher reaction temperatures up to 30 – 50 °C are used.

Amines that form sparingly soluble diazonium chlorides must be diazotized in a more diluted state; otherwise a clear solution is not obtained. For many diazoazobenzenes, concentrations as low as 0.03 mol/L are used, compared with ca. 1 mol/L for diazonium compounds of chlorobenzenes or chlorotoluenes.

Amines with a tendency to form triazenes require more acid, (e.g., 2,5-dichloroaniline requires 4 – 5 mol HCl), whereas the easily oxidizable aminonaphthols are diazotized satisfactorily only with the stoichiometric amount of acid.

Aromatic aminosulfonic acids are usually only slightly soluble in water (zwitterions), as are their diazonium salts. Sulfanilic acid may be diazotized by a standard procedure. For larger molecules, *indirect diazotization* is a better approach: the aminosulfonic acid is dissolved by the addition of an equivalent amount of sodium hydroxide solution to give the sodium salt. Sodium nitrite solution is then added, and the mixture poured into dilute ice-cooled hydrochloric acid to effect diazotation.

Diazotation of *weakly basic aromatic amines* (dinitroanilines, dinitrocyanoanilines, and heterocycles such as aminonitrothiazoles), which has gained increasing industrial importance due to the development of blue to red disperse dyes based on azo chemistry, calls for special techniques. The poor nucleophilicity of these amines requires strong electrophiles such as the nitrosonium cation, which is formed quantitatively from nitrous acid in highly acidic media like sulfuric or perchloric acid above 65 wt % acid. The highly electrophilic diazonium ions formed are stable only at very high acidities of the solvent; typically > 85 wt % of sulfuric acid is required to avoid decomposition. Reaction kinetics can be complex, and unusual dependences of rate constants on overall concentration of amine have been observed [10, B1 – B52]. Quenching the reaction mixture with ice in many cases produces a diazonium salt solution which can be further

processed in the same way as a product made by the hydrochloric acid – nitrite route.

To remove undiazotized material and byproducts *clarification* of diazonium salt solutions may be necessary. The use of a filtration aid such as diatomite is recommended; activated carbon is used to obtain the best results. The solution then usually goes directly into the azo coupling reactor. Diazonium salt is isolated only for special products, such as pure materials for reprography or the textile industry, where inert salts in the product are not tolerated.

Crystalline diazonium salts can be precipitated from solution by the addition of a solution of zinc chloride, arylsulfonate, sodium chloride, etc. Solid precipitants should be introduced gradually. In a few cases, the diazonium salt solution is added to the precipitant. Temperature, time, and stirring intensity are chosen to give crystals as large and compact as possible, to facilitate filtration. The adhering mother liquor can be removed largely by a basket centrifuge, giving residual moisture contents of 5 – 30 %, depending on the product. Some materials not suitable for centrifugation, e.g., those with platelet or needlelike crystals, may be dewatered in a hydraulic press. Continuous centrifuges enable filtration and dewatering to be done in a single operation, but care must be taken to avoid heating the diazonium salt excessively, with the consequent danger of fire when the diazonium salt is removed by the scraper blade. The yield depends on the choice of amine and the method of isolation. Tetrachlorozincates give the best results, with yields as high as 96 %.

Reaction vessels can have a volume up to and sometimes exceeding 20 m^3. Preferably, they should be glass-lined and have a cooling jacket for water or brine. With rubber- or brick-lined vessels, the only cooling method possible is addition of ice. Pipework can be made from rubber- or glass-lined steel, polypropylene, or glass-fiber-reinforced polyester resin. The filtration equipment (leaf filters, pressure filters, and filter presses) usually is made of rubber-lined steel.

Commercially important diazonium salts used to be the chlorides; the hydrogensulfates; the tetrachlorozincates, $ZnCl_4^{2-}$; the tetrafluoroborates BF_4^-; and the arylsulfonates, $ArSO_3^-$. Progress in textile dyeing consumed much of the market for these products.

Benzenediazonium chloride and its simple substituted derivatives cannot efficiently be crystallized from solution because of their high solubilities. Higher molecular mass is required to give satisfactory yields, e.g., salts with two or more benzene rings per diazonium group. The ease of decomposition of crystalline diazonium chlorides makes their isolation risky and unfavorable. Therefore, only the most stable diazonium cations are produced industrially as chlorides. Diphenylamine-4-diazonium chloride [*101-56-4*] and 4′-methoxydiphenylamine-4-diazonium chloride [*101-69-9*] had special importance because of their use as diazo components of blue dyes. The amino group in the *para* position has a stabilizing effect, giving the diazonium chlorides good storage properties which surpass those of most other industrial diazonium salts.

Diazonium hydrogensulfates are more sparingly soluble than the corresponding chlorides and can be precipitated from the solution obtained in a diazotization reaction by adding sulfuric acid or sodium hydrogensulfate (in practice, 78 % sulfuric acid plus sodium sulfate). The second method of isolation has proved to be very successful in the production of azobenzene diazonium salts.

Diazonium tetrachlorozincates display extremely good crystallization properties. They have high solubility in water or dilute mineral acids but not in concentrated sodium chloride solution, which allows their isolation in good yield. Their large, hard, compact crystals are suitable for further processing and are usually very stable, so that these products are the most common solid diazonium salts.

The first step is the clarification of the diazonium salt solution by filtration. Over a period of ca. 1 h, zinc chloride (0.6 – 0.7 mol per mole of diazonium salt) is added in the form of a ca. 65 % technical-grade solution. For the less-soluble tetrachlorozincates, a dilute solution is used to avoid formation of an amorphous precipitate. Addition of 10 – 20 vol % of sodium chloride completes the precipitation.

Tetrachlorozincates may also be produced from the solutions in concentrated sulfuric acid that are obtained by adding nitrosyl diazotization products to ice. Zinc chloride solution

and sodium chloride are added, precipitating the tetrachlorozincate. However, usually the diazonium hydrogensulfate is precipitated, filtered off, dissolved in water, and then precipitated as the tetrachlorozincate.

Diazonium tetrafluoroborates may be obtained from diazonium salt solutions in hydrochloric acid by addition of tetrafluoroboric acid or its salts, usually the sodium salt. For good yields, an excess of 30 – 50 % is required. Solubilities are similar to those of the tetrachlorozincates, but crystallization properties and yields are inferior. They are used in industry because they are less explosive than other salts.

Diazonium arylsulfonates are obtained by addition of arylsulfonic acids or their alkali metal salts to diazonium salt solutions. If necessary, precipitation can be completed by addition of sodium chloride. Their solubility, for a given cation, depends strongly on the type of arylsulfonic acid.

Drying of diazonium salts must be carried out gently because of their instability. Usually drying cabinets with trays are ventilated with air at ca. 45 – 70 °C and provided with emergency water sprays that come into operation at a predetermined temperature. Vacuum drying is avoided because the gas that is evolved when the material decomposes can destroy equipment. For safety reasons, no drying processes are used that subject the product to mechanical stress.

Only a few diazonium salts are stable enough to be dried in the form in which they are produced. Many are first blended with inert salts, such as sodium sulfate or sodium chloride, to reduce the danger of explosion. Any adhering acid is neutralized by mildly alkaline materials such as borax or magnesium oxide.

The *final processing* of a diazonium salt includes grinding and other processing if the diazonium salt is to be used as a dye intermediate, i.e., incorporation of additives, adjustment of product content, and removal of fines.

Additives suppress undesirable properties in the product and widen the range of uses. The prime concern is to reduce the risk of explosion, e.g., by addition of inert materials such as sodium chloride or sodium sulfate. Another approach is to add compounds with a large heat of fusion or vaporization. In practice, only hydrates, usually aluminum sulfate hydrates, are used [35]. These methods desensitize the products, rendering them completely safe even under severe stress. Some metal salts, such as chromium acetate or aluminum sulfate, or boric acid [36], [37] can be added as buffering agents. Metaboric acid or boric anhydride improves the stability and avoids discolorization or caking [38].

3.1.3. Other Methods of Preparation

Other methods of producing diazonium salts have some importance, e.g., the introduction, replacement, and modification of substituent groups in diazonium salts that are already formed (Section 4.1), and the reaction of nitrous acid with arylamine-*N*-sulfonic acids. Weakly basic amines may be diazotized more easily in this way than in the unsubstituted form, probably because of the solubility imparted by the *N*-sulfonic acid group.

$$\mathrm{ArNHSO_3H + HNO_2 \longrightarrow ArN{\equiv}N^+ + HSO_4^- + H_2O}$$

3.1.4. Uses

Solid diazonium salts with blended additives are used mainly for the manufacture of developing dyes for textile dyeing and printing (→ Azo Dyes, Chap. 3., with tables of trade names, chemical constitutions, and Colour Indexes in → Azo Dyes). The industrial manufacture of stabilized diazonium salts according to the processes described above is declining due to the continuing displacement of developing dyes by reactive dyes. However, diazonium salts prepared as intermediates for azo pigments continue to play an important role in the color industry. Another application used to be diazotype photocopying processes (→ Imaging Technology, Chap. 3.2.1.). Many other uses of diazonium salts are discussed in the following sections.

3.2. Diazotates

Diazonium ions are capable of accepting a hydroxyl ion to form a diazohydroxide which is deprotonated to yield a diazotate anion. [4], [6].

The reaction takes place in weakly alkaline media if strongly electron withdrawing substituents are present which enhance the Lewis acidity of the diazonium ions. For less acidic ions strongly alkaline pH is required. *Z*-Diazotates, formed under kinetic control are converted to the more stable *E*-diazotates in strongly alkaline solution. [39] Experimental evidence points to a direct rearrangement rather than a dissociation/addition mechanism [4].

The rate of conversion again depends on the substitution pattern and is fastest for more acidic compounds [40]. Only *E*-diazotates are used in industry. At acidic pH diazotates form diazonium ions in the reverse of their formation. This reaction is the reason for their former use in the textile printing industry, where they served as a latent form of the diazonium ion ("Rapid Fast Dyes"). Sodium and potassium diazotates are crystalline substances that store well. They decompose on heating, though not violently. The industrial use of this class of compounds has been greatly diminished by reactive dye textile printing. For an overview, see [12, 10/3], [34, C1].

3.3. Diazosulfonates

Diazosulfonates have been known since 1869, but due to the lack of appropriate analytical methods their structure was a matter of discussion for years. Diazosulfonates exist in two isomeric forms. The stable *E* (*anti* or *trans*) isomer and the labile *Z* (*syn* or *cis*) isomer.

Formation, isomerization, kinetic investigations and photo-isomerization were studied extensively in the 1950s and 60s [41–43]. In the S-coupling reaction of an aromatic diazonium salt with SO_3^{2-}, primarily the *Z* isomer is formed, which rearranges to the *E* isomer. The labile *Z* isomer is in equilibrium with the starting diazonium compound.

Thermal or photochemical decomposition proceeds via an ionic or radical pathway. The presence of diazonium ions can be detected by coupling reactions with, e.g., β-naphthol. ESR studies proved the existence of radicals on photolysis of diazosulfonates [44]. Industrial applications of diazosulfonates are mainly based on their conversion to reactive diazonium ions and subsequent coupling reactions [45].

Properties. The sodium diazosulfonates are yellow to orange solids and crystallize well. The *Z* isomers have a tendency to explode on isolation as dry material [44], [45]. The *E* isomers usually exhibit considerable stability and can be stored for years without decomposition. For purification they can be recrystallized from water, although prolonged heating should be avoided. Unsubstituted *E*-diazosulfonates and those with electron-withdrawing substituents are usually stable towards dissociation. Only diazosulfonates with electron-donating substituents, e.g., those derived from 4-aminodiphenylamine, generate diazonium ions and form azo dyes in presence of a coupling component. Reducing agents like dithionite and excess of sulfite convert diazosulfonates at least to some extent (depends on excess and quantity of reducing agent used) into phenylhydrazine-*N*-sulfonic acids, which are intermediates in the synthesis of phenylhydrazines. Reduction of isolated diazosulfonates can also be achieved by catalytic hydrogenation [46].

Preparation. Diazosulfonates are prepared by the reaction of an aromatic diazonium salt (prepared in situ) with alkali metal sulfite solution. Usually the diazonium salt solution is added to a solution of sodium sulfite at below 10 °C. Since only the sulfite ion but not the hydrogensulfite ion is suitable for S-coupling, a neutral to weakly alkaline medium is required, that is, the pH should be kept below 8. This can be achieved by the parallel addition of sodium carbonate or sodium hydrogencarbonate.

Immediately after mixing the two solutions, the color turns yellow, indicating product formation. It is recommended to continue stirring after complete addition at slighty elevated temperature (30 – 40°C) for at least one hour, to ensure complete isomerization to the *E* isomer.

More alkaline conditions favor decomposition; in addition, diazotates are formed in a side reaction. To avoid partial reduction to the arylhydrazine-*N*,*N*′-disulfonic acid, only a slight excess (ca. 10 %) of alkali metal sulfite has to be applied. Due to the good solubilities of the diazosulfonates, it is recommended to use the highest possible concentration of diazonium salt solution to achieve acceptable yields. Since potasium diazosulfonates are less soluble, it is sometimes advantageous to use them instead of sodium sulfite. Yields can also be increased by the addition of sodium chloride during precipitation.

The above-mentioned reaction finds broad application, and a large number of diazosulfonates have been synthesized [44], [45].

Uses. Sodium 4-dimethylaminobenzene-*E*-diazosulfonate [*140-56-7*] has fungicidal properties and is used as a soil disinfectant (Dexon) to combat damage to seedlings and roots. Diphenylamine-4-*E*-diazosulfonate and its 4′-methoxy derivative are used in textile printing for producing blue and black shades. They are marketed as mixtures with the coupling components, usually 2-hydroxynaphthalene-3-carboxylic acid anilide. The azo dyes are formed by steaming the prints. Textile prints of *E*-diazosulfonates and Naphtol AS components can also be developed by irradiation. Other applications have been found in reprography [47]. Applications of polymer-bound diazosulfonates as photoresists in offset printing have been described [44]. Diazosulfonates can be considered as thermally stable sources of diazonium salts and and thus could have applications in analytical quick assays [44].

3.4. Triazenes

Triazenes are formed by N-coupling of diazonium ions. Their chemistry forms a broad subject that is discussed in detail in [48].

In most cases in solution, a true pH-dependent equilibrium is observed which can be used to regenerate the diazonium ions. For R′ = H tautomerization is possible and results in mixed diazonium ions for the case R = Ar′.

Properties. The stability of triazenes covers a wide range; most compounds will rearrange in weakly acidic media to form aminoazo compounds, while some compounds like 2,2′,4,4′,5,5′-hexachlorodiphenyltriazene are almost inert to aqueous mineral acid [49].

In alkaline media triazenes are stable. Protic compounds can be deprotonated to form intensely colored salts.

Preparation. The only method of importance in triazene manufacture is N-coupling in buffered solutions or suspensions of the amine. Low reaction temperatures (0 – 10 °C) are required to avoid decomposition. Products usually precipitate from the reaction solution; in some cases salting out or spray drying is used to isolate the more soluble products. The reaction of diazonium salts with secondary aliphatic amines takes place smoothly and usually with an excellent yield; industrially relevant triazenes are produced from amines with solubilizing groups such as sarcosine and methyltaurine.

CH_3NHCH_2COOH	$CH_3NHCH_2CH_2SO_3H$
Sarcosine	Methyltaurine
[*107-97-1*]	[*107-86-6*]

A good example is the preparation of sodium 3-methyl-1-(5-chloro-2-methoxyphenyl)-3-(carboxylmethyl)triazene. 4-Chloro-2-amino-1-methoxybenzene hydrochloride is mixed with water, and 32 % hydrochloric acid is added. Ice is added to bring the temperature to 0 °C, and nitrite is then added as a 30 % solution, maintaining the temperature at 0 °C by further

ice addition. After the diazotization, a small amount of diatomite is added, and the liquid is filtered with a clarifiying press. A mixture is prepared of sarcosine, sodium carbonate, sodium chloride, water, and ice. The diazotized solution is added over ca. 30 min, keeping the temperature at 0 °C by ice addition. The precipitated triazene is filtered and dried at 80 °C.

When diazonium salts are treated with primary or secondary aromatic amines, triazene formation competes with azo coupling. The dominant pathway depends on the nucleophilicity of the amine. If the nucleophilicity is not increased by electron-releasing substituents or fused rings, triazene is formed preferentially. Triazene formation is also favored by electron-withdrawing substituents and when the position *para* to the amine group is occupied. In cases where azoamino and triazene formation compete, high pH of the reaction medium favors the triazene pathway, because cleavage and rearrangement of the triazene chain is catalyzed by acid. Secondary aromatic amines have a greater tendency to form triazenes than the corresponding primary amines. Water-soluble triazenes are formed without difficulty from **1** and especially from **2** and **3**.

1

2

3

The sodium derivative of 3-methyl-1-(4-nitro-2-methoxyphenyl)-3-(4-sulfo-2-carboxyphenyl)triazene (**4**) is prepared by first diazotizing 5-nitro-2-amino-1-methoxybenzene at 10 – 15 °C in dilute sulfuric acid and adding this to a solution of 2-methylamino-5-sulfobenzoic acid that has been neutralized with sodium hydroxide solution and mixed with calcium carbonate. The pH is adjusted to ca. 12 with sodium hydroxide solution, thus precipitating calcium sulfate, which can be filtered off. The filtrate is then spray dried [50, ; p. 25.]

4

Symmetrical 1,3-diaryltriazenes that are to be rearranged to *p*-aminoazo compounds, can be prepared by reacting the amine with half an equivalent of nitrous acid in a moderately acidic medium. The reaction is usually carried out with an excess of amine, which acts as a reaction medium and speeds up the rearrangement. [11].

Uses. Like diazotates, triazenes were also used as diazonium precursors for developing dyes ("Rapidogen Dyes"), but again this application has declined due to the emergence of more efficient dyes and procedures. Some triazenes are active against bacterial and especially against protozoal infections. Berenil [*536-71-0*] was developed to treat diseases caused by trypanosoma and babesias.

Berenil

1-Aryl-3,3′-dimethyltriazenes can act as prodrugs for 1-aryl-3-methyltriazenes, which are efficient in vivo antitumor agents. One of these compounds, Dacarbazine, is used in the treatment of melanoma and soft tissue sarcoma [51].

Dacarbazine

3.5. Other Aromatic Diazo Compounds

Diazotized *o*- and *p*-aminophenols (**5**) exist only in mineral acid solution. The diazonium group renders the hydroxyl group much more acidic, increasing the ionization constant by several orders of magnitude, e.g., from 10^{-10} for phenol to 10^{-3} for **5**. The mesomeric system formed is known as quinone diazide (**6**).

5 **6a** **6** **6b**

Quinone diazides are also known as diazophenols in the literature, yet they differ distinctly in their chemical properties from diazonium salts. Yellow in color, the compounds are sparingly soluble in water and quite explosive, especially when nitro groups are present in the molecule. Picramic acid [*96-91-3*] may be diazotized to give dinitrobenzoquinone diazide [*7008-81-3*] (**7**), which is used as a detonator.

7

Quinone diazides can be employed in the the Sandmeyer reaction, and they form azo dyes. However, their reactivity in coupling is considerably less than that of the corresponding substituted diazonium salts. 2,2′-Dihydroxyazo dyes are formed by coupling with substituted phenols and are capable of forming metal-complex dyes (→ Azo Dyes, Chap. 3.2.1.4. and → Azo Dyes, Chap. 4.1.8.). By the action of light, naphto-*o*-quinone diazides are converted to indene-carboxylic acids, with liberation of nitrogen and ring contraction [11]; thus, they can be used in reprography.

Quinone diazides in the benzene series are formed through diazotization of aminophenols. In some cases, buffering with sodium acetate is necessary. The products are used in the form of a suspension to avoid the danger of explosion.

When *o*-aminonaphthols are treated with nitrite in a mineral acid medium, they are oxidized to naphthoquinones. Diazotization can be achieved in weakly acidic solution in the presence of a small amount of a metal salt, preferably of copper(II) [12, 10/3], [52], [85]; under these conditions the reaction proceeds smoothly. The naphthoquinone diazides formed are stable compounds; for example, they can be crystallized from boiling water, be nitrated, or be chlorinated (see page 13). Moist products can be stored and marketed safely. For details on the production of 4-diazo-3,4-dihydro-3-oxo-naphthalene-1-sulfonic acid [*4857-47-0*], see [52]. Naphthoquinone diazides are important starting materials in the manufacture of metal-complex dyes and are used in reprography (especially films for offset litho printing and IC manufacture (→ Imaging Technology).

Aryldiazo ethers, esters, sulfides, thioethers, sulfones, cyanides, and phosphoric esters have very few practical applications. One or two of these have been suggested as polymerization catalysts and modifiers. The acaricide Milbex [*2274-74-0*] is a tetrachloroaryldiazo thioether.

Milbex

3.6. Analysis

The best way to detect aromatic diazo compounds is by the azo coupling reaction. The substance under investigation is treated with (1) a phenolic azo component, such as resorcinol, β-naphthol derivatives or H-acid dissolved in sodium hydroxide or carbonate solution, or (2) an aromatic amine capable of azo coupling dissolved in dilute acetic acid. The most convenient method is to use a spot test [53].

E-Diazotates and triazenes are converted to diazonium salts by acid treatment, which is not successful in all cases since some triazenes are very stable even under these conditions. Non-coupling *E*-diazosulfonates may be converted to diazonium salts by treatment with oxidizing agents. To identify the aromatic part of the

molecule, either direct spectroscopy (IR, NMR, MS) is used or the diazonium salts are converted to chlorinated aromatic compounds by the Sandmeyer reaction, which are then identified by standard methods. The universal chemical method for quantitative analysis of diazonium salts is controlled decomposition by treatment with acid and copper(I) ions and measurement of the nitrogen evolved [54], [55]. In industry, diazonium salts and their solutions are often analyzed by titration. The diazonium salt solution is gradually added to a known amount of coupling component, e.g., R salt (disodium 3-hydroxy-2,7-naphthalenesulfonate [*135-51-3*]), β-naphthol, or 2,4-diaminotoluene. The end point is detected by the disappearance of the coupling component or the appearance of the diazonium salt, as detected by spot test methods. Unreactive or easily decomposed diazonium compounds may be treated with an excess of the coupling component, followed by back-titration. Quantitative analysis can also be accomplished by spectophotometry provided internal or external standardization is possible. The products must be fairly pure so that secondary or decomposition products do not interfere with the absorption maximum of the diazo compound.

4. Diazo Reactions

From a practical point of view, the most important reactions of the diazo compounds can be placed in three groups: (1) reactions in which the diazo group is retained but substituents are introduced or replaced, (2) reactions in which the diazo group is modified, and (3) reactions in which the diazo group is replaced.

4.1. Chemical Transformation with Retention of the Diazo Group

Substituents can be introduced or replaced without changing the diazo group.

Electrophilic Substitution. The diazonium group is the strongest electron-withdrawing substituent known. Therefore, electrophilic substitutions on the same nucleus are very difficult to achieve and largely of theoretical interest only. Under special circumstances, halogen atoms or nitro or sulfonic acid groups may be introduced into the aromatic ring. An example is the production of 6-nitro-1-diazo-2-naphthol-4-sulfonic acid [*5366-84-7*] [56].

Nucleophilic Substitution. Owing to the strongly electron-withdrawing character of the diazonium group, nucleophilic replacement of *ortho* and *para* substituents is possible. Ease of replacement increases in the order SO_3H, OCH_3, Cl, NO_2, and $-N{\equiv}N^+$. In the benzene-1,4-bis(diazonium) ion, one of the diazonium groups can be easily replaced by a halogen or hydroxyl group. Replacement of a nitro group can take place only in the presence of an additional electron-withdrawing substituent; therefore, solutions of *o*- and *p*-nitrodiazonium ions, which are heavily used in industry, are stable under typical handling conditions.

On the other hand, the *o*-nitro group in diazotized 2,4-dinitroaniline can be replaced by nucleophiles. This reaction muddies the color of the pigment derived from 2,4-dinitroaniline and β-naphthol during production. Care has to be taken to avoid these side reactions when diazonium salts with strong electron-withdrawing substituents are prepared or converted.

The replacement of chlorine by a hydroxyl group is used in the manufacture of 4-hydroxy-3,5-bis(diazo)benzenesulfonic acid, a component for complex-forming azo dyes.

4.2. Reactions at the Diazo Group

Azo Coupling. Diazonium salts combine with many electron-rich aromatic compounds and compounds with active CH or NH groups to form azo compounds, which may tautomerize subsequently. Coupling with phenols, aromatic amines, and acetoacetarylides is most important for the dyes and pigments industry; for a detailed discussion see → Azo Dyes.

Formazan Formation. Diazonium ions react with functional groups carrying active hydrogen as mentioned above. Starting from an aldehyde hydrazone, the product is a formazan:

Compounds with a doubly activated methylene group, e.g., acetoacetyl compounds, first form an arylhydrazone, which can react in an alkaline medium with another diazonium ion to give the formazan. In this reaction one of the two activating radicals is split off (Japp – Klingemann reaction)

R, R' = CHO, $COCH_3$, CN, $COOCH_3$, $CONH_2$, COOH

By means of kinetic control, unsymmetrical formazans can be produced by using two different diazonium salts, provided their rates of reaction differ.

Formazans are intensely colored compounds. They show amphiphilic properties and hence behave as indicators with changes in pH. For this reason and because of their poor lightfastness, simple formazans are rarely used for textile dyeing. However, they are used in photography, e.g., for yellow filters and color developers.

Formazans form heavy-metal complexes, the industrially relevant ones being those of Co, Cr, Cu, and Ni. These complex dyes have considerably improved stability, owing to the presence of additional functional groups (OH, COOH) in the *ortho* positions of the aryl radicals attached to the nitrogen atom, which act as ligands for the metal ion. Excellent lightfastness and low sensitivity to acids and bases make some of these complexes valuable textile dyes (→ Metal-Complex Dyes).

Cyclization Reactions. Reactive *ortho* substituents react with diazo groups to give heterocyclic products. [57], [58]. This pathway is exploited to convert diazotized *o*-toluidines to indazoles. Although the parent substance *o*-toluidine and derivatives with an electron-releasing substituent undergo this reaction only to a minor extent, the mononitro derivatives in acetic acid solution or the dinitro derivatives in sulfuric acid solution give high yields of indazole. A frequent side product is a 3-arylazoindazole. *o*-Aminobenzamides give benzotriazines under diazotizing conditions e.g. Azinphos-methyl [*86-50-0*], a component of the insecticide Gusathion.

Indazole

Azinphos-methyl

Benzotriazole

o-Diamines also do not yield diazonium salts; instead, they are converted to cyclic triazoles when treated with nitrous acid. The preparation of benzotriazole and its simple derivatives is best carried out in dilute acetic acid [59]. Nitrite is added at once, and no cooling is required. Unlike the open-chain triazenes, triazoles appear to be stable toward mineral acid. Triazoles can form salts with acids or bases. Benzotriazoles and tolutriazoles are corrosion inhibitors.

Reduction. Diazonium salts and covalent diazo compounds such as diazotates, diazosulfonates, diazosulfones, and triazenes can be reduced to arylhydrazines. Most common reducing agents are effective. Electrochemical reduction has also been described [60], [61]. Tin(II) chloride reduces diazonium salts under mild conditions (low temperature) in highly acidic media and provides a convenient method for aromatic hydrazines. Due to the large excess of tin(II) chloride which finally enters the wastewater, this method is limited to laboratory scale. In industry, sodium sulfite and sodium hydrogensulfite are used almost exclusively. When the reaction proceeds sluggishly, it can be brought to completion by the addition of zinc dust. The sulfite reduction of aryldiazonium salts to arylhydrazines takes place stepwise via aryldiazosulfonates (**8**), arylhydrazine-α, β-disulfonic acids (**9**), and arylhydrazine-β-sulfonic acids (**10**).

Reactions (1) and (2) take place in a weakly acidic to weakly alkaline medium, reaction (3) in weak to moderately strong acid, and reaction (4) in the mineral acid range. Commercial 40 % sodium hydrogensulfite solution is converted to sulfite by addition of sodium carbonate or sodium hydroxide solution. Each diazonium cation requires two sulfite equivalents for reduction. Usually 10 – 20 % excess of sulfite is applied to achieve optimum conversion and yields. In the preparation of unsubstituted phenylhydrazine, 102 % of the theoretical amount suffices [26].

The diazonium solution or suspension is added to the sulfite solution. If no electron-withdrawing substituents are present, the mixture is heated at 60 – 80 °C to give **10**. During reduction, the pH should be held between 5 and 7 by means of inorganic bases. Colored impurities can be reduced with a little zinc dust. At this stage, if necessary, a charcoal filtration may be carried out to remove tarry or insoluble materials.

Hydrolysis of the arylhydrazine-α, β-disulfonic acid to arylhydrazine-β-sulfonic acid already takes place under mild acidic conditions. To minimize salt generation it is also possible to reduce the diazosulfonate in good yields catalytically with hydrogen in the presence of Ni or noble metal catalysts to arylhydrazine-β-sulfonic acid.

The second sulfonic acid group is much more firmly bonded than the first, and the conversion to arylhydrazine requires warming under strongly acidic conditions, usually accomplished by adding concentrated hydrochloric acid or sulfuric acid to the arylhydrazine-α, β-disulfonic acid or arylhydrazine-β-sulfonic acid and heating at 6 – 100 °C. In some cases solvents were found to be advantageous in hydrolysis [62].

Arylhydrazines with sulfonic acid groups in the aromatic nucleus precipitate as sparingly soluble zwitterions. If there are no sulfonic acid groups present, the hydrazines are isolated as sulfates or hydrochlorides. Free hydrazines can be precipitated by neutralizing the acidic solution solution with alkali. If solid, they are filtered off; if liquid, they are dissolved in solvents and isolated by fractional vacuum distillation.

Phenylhydrazine hydrochloride can also be manufactured by a continuous process [33], but most arylhydrazines are made by batch processing. Arylhydrazines are starting materials for pyrazolones, which serve as dye precursors. They react with dioxo compounds to give azo dyes (→ Azo Dyes, Chap. 2.4.4.). In addition, phenylhydrazines are versatile building blocks for heterocycles such as indoles, triazolinones, pyrazoles and pyridazinones, which are valuable intermediates in the pharmaceutical and agrochemical industries [18], [63–65].

Sulfentrazone

Celecoxib

4.3. Dediazotization (Replacement of the Diazo Group)

The term dediazotization describes reactions of diazo- and diazonium compounds in which the N_2 molecule is a reaction product. In the following, dediazotization of arenediazonium compounds is discussed. The diazo group can be replaced by a hydrogen, hydroxyl, halogen, cyanide group, etc.

Hydrodediazotization. The replacement of the diazo group by hydrogen is not only used on a laboratory scale but finds industrial application for the manufacture of compounds that are not accessible by direct electrophilic aromatic substitution reactions. For example, 1,3,5-trichlorobenzene can be prepared by chlorination of aniline, diazotization and hydrodediazotization. Treatment of diazonium salts in boiling ethanol leads to the desired product, but quite often ethoxydediazotization occurs. Excellent results can be obtained by using hypophosporous acid as the reducing agent. For some special purposes salts, esters, and amides of formic acid or even formic acid itself are used [66]. For example, 3-hydroxynaphthalene-1-sulfonic acid [*6357-85-3*], a coupling component for dyes, can be manufactured in excellent yields.

Hydroxydediazotization. Thermal decomposition of diazonium ions in aqueous acid gives transient aryl ions, which react with water to give phenols:

$$Ar{-}N^+ \equiv N \longrightarrow Ar^+ + N_2$$
$$Ar^+ + HOH \longrightarrow ArOH + H^+$$

In the presence of other nucleophiles Z^-, side reactions can occur:

$$Ar^+ + Z^- \longrightarrow Ar{-}Z$$

Therefore, diazotization and dediazotization are best carried out in sulfuric acid solution. The simplest method is to heat the diazonium salt solution to 80 – 100 °C, but the products obtained are usually not very pure. Higher yields and purities can be achieved by adding the diazonium salt solution to hot (boiling), dilute sulfuric acid. To avoid diazo coupling of the phenol with unconverted diazonium salt, the acidity of the reaction mixture should be sufficiently high. At sulfuric acid concentrations of 45 – 60 %, reaction temperatures can be as high as 118 – 142 °C. The sulfuric acid can be partly replaced by sodium sulfate. Sometimes Cu salts are used in the decomposition reaction [67].

During hydroxydediazotization, side products, sometimes dark in color and insoluble, are often formed in considerable amounts, e.g., diphenyl sulfates, diphenyl ethers, hydrocarbons, nitrosophenols, indazenes, dioxazines, hydrazobenzenes, and arylsulfonic acids. This formation of diazo resin, which visibly builds up during the course of the reaction, can be minimized by careful diazotization and avoidance of excess nitrite. Continuous removal of the phenol, e.g., by steam distillation, is favorable. Conducting the reaction in a continuous manner can also improve yield and quality. Yields are usually in the range of 50 – 75 % but can exceed 90 % in some cases if phenols are continously removed from the reaction mixture [6, ; pp. 6, 225], [67]. Improved yields can sometimes be achieved by dissolving the formed phenol in an organic solvent such as xylene.

The preparation of hydroxyanthraquinones from aminoanthraquinones can be accomplished in concentrated or fuming sulfuric acid. Diazonium salts that do not react in sulfuric acid even at elevated temperatures can be converted in phosphoric acid at ca. 200 °C.

The industrial importance of hydroxydediazotization lies not only in the transformation of an amino group into a hydroxyl group but also provides a method to manufacture chloro- or nitro-substituted phenols and cresols at the *meta* position, e.g., the preparation of 2,3-dichlorophenol [*576-24-9*] [68] or 4-methyl-3-nitrophenol [*2042-14-0*].

Chloro- and Bromodediazotization. Treatment of aromatic diazonium salts in aqueous solution with chloride or bromide ions in presence of the corresponding Cu halide leads to aryl chlorides and bromides. The reaction

has been known since 1884 and is called the Sandmeyer reaction; the following mechanism is proposed:

$$2\,ArN_2^+ + CuCl_2^- \longrightarrow Ar^\bullet + N_2 + CuCl_2$$

$$Ar^\bullet + CuCl_2 \longrightarrow ArCl + CuCl$$

The first step is the reduction of the diazonium group by electron transfer from the CuX_2^- and formation of an aryl radical. Finally the radical abstracts a halogen from the copper(I) chloride to give the arylhalogenide and CuX. Azo compounds and diphenyls can be formed as side products in Sandmeyer reactions.

$$2\,ArN_2^+ + CuCl \longrightarrow ArN{=}NAr + N_2 + 2\,Cu^{2+} + 2\,Cl^-$$

$$2\,ArN_2^+ + + CuCl \longrightarrow Ar{-}Ar + 2\,N_2 + 2\,Cu^{2+} + 2\,Cl^-$$

These can be minimized by increasing the concentration of halide in the solution. Enough hydrochloric acid should be added that its concentration in the reaction mixture does not fall below 5 – 10 wt % during addition of the diazonium salt solution. Additionally, the concentration of the diazonium salt should be kept as high as possible.

In industry, a molar ratio of copper(I) halide to diazonium salt from 1/10 to 1/5 is used, although in some cases considerably more catalyst is required. For example, one molar equivalent is used in the manufacture of 2-chloro-5-nitrophenol [*619-10-3*] from 5-nitro-2-aminophenol. Copper(I) chloride is sparingly soluble in water and is usually used in the form of the more soluble chloro complex. The Sandmeyer reaction can be conducted in glass-lined, rubber-coated, or brick-lined (acid resistant) vessels. The filtration equipment and pipework are made of rubber-lined steel, and the pipework is often made of suitable plastic. Reaction temperatures are usually in the range of 10 – 30 °C, although in a few instances, they are higher, e.g,. 75 °C for 4-chlorotoluene-2-sulfonic acid. The reaction product is isolated by steam distillation or filtration. The copper is precipitated from the mother liquor and recycled.

3-Chlorotoluene [*108-41-8*] is manufactured on an industrial scale by a Sandmeyer reaction [70]. The Sandmeyer reaction may also be carried out with copper(I) bromide and hydrobromic acid [71].

Cyanodediazotization. Replacement of the diazonium group by cyanide in presence of Cu catalysts to form aromatic nitriles (cyano Sandmeyer reaction) is similar to the reaction with Cl^- and Br^-. The reaction is usually conducted in a neutral medium to avoid liberation of HCN.

$$ArN_2^+ + CN^- \longrightarrow ArCN + N_2$$

Because copper(I) cyanide is insoluble, sodium copper(I) cyanide, $NaCu(CN)_2$ is used as catalyst. The amount of catalyst required is larger compared with chloro-dediazotization, usually 25 – 30 mol %. Reactions can be performed at ambient temperature. The large excess of cyanide (180 – 300 % of theory) may result in unwanted diazocyanides. To minimize this side reaction, only part of the alkali metal cyanide is added with the Cu catalyst; then the remaining quantity is added in portions along with the diazonium salt solution, e.g., in the production of 5-chloro-4-nitro-2-methylbenzonitrile [72].

Iodo- and Fluorodediazotization. Unlike aryl chlorides and bromides, which are accessible from the Sandmeyer reaction, aryl fluorides cannot be achieved in this way. In case of the iodo derivatives, no copper(I) catalyst is required since the redox potential of iodine is sufficient for electron transfer to the diazonium salt. It has been proposed that initially aryl radicals as well as iodine and triiodide are formed followed by coupled chain reactions [6, ; p. 236].

$$ArN_2^+ + I^- \longrightarrow ArI + N_2$$

For aryl iodides the reaction is carried out in mineral acid, usually hydrochloric or sulfuric acid, and proceeds much faster than with the other halides. A concentrated aqueous solution of alkali metal iodide is added to a diazonium salt solution. Inverse addition is also possible. For each mole of diazonium salt, 1.1 – 2.0 equivalents of iodide is used. Elevated reaction temperatures to increase rate of conversion are not required. Volatile aryl iodides may be recovered by steam distillation. Less volatile products are isolated by filtration or extracted by solvents such as toluene. The plant growth regulator 2-iodo-3-nitrobenzoic acid [*5398-69-6*] is manufactured on commercial scale by iododediazotization [69].

If solutions of diazonium fluorides in anhydrous hydrofluoric acid are warmed, fluoroaromatics are obtained. The diazonium fluorides are prepared by dissolving the amine in 2 – 3 equivalents of hydrofluoric acid and diazotized by adding dry sodium nitrite at ca. 0 °C. When the reaction mixture is heated to reflux (ca. 30 °C), nitrogen is released. The reaction takes place smoothly over several hours.

Another important route to fluoroaromatics is the thermal decomposition of neat diazonium fluoroborates (Balz – Schiemann reaction).

$$(ArN{\equiv}N)^{+}BF_4^{-} \longrightarrow ArF + N_2 + BF_3$$

Diazoniumtetrafluoroborates are precipitated by addition of $NaBF_4$ to a cold solution of diazonium salt prepared as usual with sodium nitrite in hydrochloric acid. The BF_4^- salts are comparatively stable and can be isolated in high yields.

Mercapto- and Chlorosulfodediazotization. Thiophenols can not be synthesized by a similar procedure to phenols since the thiophenol catalyzes homolytic dediazotization. However they can be synthesized by treating sodium disulfide with diazonium salt to form a diaryl disulfide, which can be reduced to the thiophenols by means of Zn – acetic acid or Fe – H_2SO_4 and other reducing agents. Another route to thiophenols is the reaction of a diazonium salt solution with potassium ethylxanthogenate [6, ; p. 227], [73] and subsequent alkaline hydrolysis of the intermediate formed. The dediazotization is carried out at elevated temperature to immediately decompose the unstable intermediates (appropriate care has to be taken to avoid accumulation). On acidification, thiophenols are obtained in reasonable yields (63 – 75 %).

Aromatic sulfochlorides are of industrial importance as precursors in the manufacture of sulfonamides, alkyl aryl sulfones, etc. They can be prepared from diazonium salts and sulfur dioxide. Copper(I) chloride is used as a catalyst.

Catalyst: Cu(F)

The reaction is carried out under reaction conditions that exclude formation of diazosulfonates (either strong hydrochloric acid or in the absence of water). Sulfur dioxide is present in large excess. Electron-withdrawing substituents in the aromatic nucleus favor the reaction and improve the yield. The sulfochlorides can be reduced to thiophenols by means of zinc – sulfuric acid. Methyl-2-*tert*-butyl-5-thiophenol is thus synthesized and can be used as stabilizer for vinyl chloride polymers, as a chain-transfer agent, and as a peptizer [74].

Nitrodediazotization can be applied if a nitro group is to be introduced into an aromatic nucleus which due to the substitution pattern cannot be easily synthesized by direct nitration. The reaction is performed with sodium nitrite in neutral or weakly alkaline medium in the presence of a Cu catalyst . Generous proportions of nitrite and catalyst are necessary: 5 mol of sodium nitrite and equimolar quantities of catalyst per mole of diazo compound. Catalysts used include copper powder, CuO, $CuSO_4$, $CuCO_3$, and $Cu_3(SO_3)_2 \cdot 2\,H_2O$, the latter being especially efficient. If electron-withdrawing substituents are present in the substrate, no catalyst is required.

Acyldediazotization. Diazonium salts are transformed with aldoximes into aryl oximes which are hydrolyzed to ketones. A copper sulfate/sodium sulfite catalyst is essential. In most cases, yields are moderate.

Heck Vinylation and Cross-Coupling Reactions. Palladium-catalyzed vinylation (Heck reaction) and cross-coupling reactions are versatile synthetic methods for C–C coupling [75–77].

Apart from aryl and vinyl halides, which represent the classical electrophiles in the Heck reaction, its synthetic scope has been broadened by succesful application of other substrates, e.g., benzoic anhydrides, aroyl chlorides, and in particular arenediazonium salts [78].

Diazonium tetrafluoroborates react with various olefins in alcohols in the presence of $Pd-CaCO_3$, or $Pd(OAc)_2$ with additional $CaCO_3$ as base under mild conditions to give substituted styrene derivatives in good to excellent yields (61 – 93 %).

This method furnishes a convenient route to cinnamic acid derivatives, which are of industrial importance as UV absorbers, as antioxidants, and as key intermediates for pharmaceuticals, agrochemicals, and fragrances [79]. Tetraaryls and extended conjugated aromatic systems have been synthesized by twofold Heck reaction of bis-diazonium salts with acrylates and styrene or twofold cross-coupling with phenylboronic acid [81]. Fluorescent whitening agents have been synthesized by Heck vinylation of e.g. diazotized 2-aminobenzenesulfonic acid with 4,4′-divinylbiphenyl [80].

Other Reactions. Due to their high reactivity, diazo and diazonium compounds are capable of reacting in manifold ways and with various other substrates to yield, e.g., biphenyls via Gomberg – Bachmann reaction, aryl azides, aryl isocyanates, arylarsonic acids (Bart reaction), or carbonylation products. Details of these and other reactions are given in [6–10].

5. Environmental Protection

In general, no problems arise with waste gases from the manufacture of diazo compounds or from industrial diazo reactions. Larger quantities of waste gases occur during manufacture of certain azobenzenediazonium salts and Sandmeyer nitrile synthesis due to the excess of nitrite used or contamination of liberated nitrogen with hydrogen cyanide. These substances can be removed by alkali washing or by treatment with oxidizing reagents.

The wastewater contains dissolved reaction and decomposition products together with quite a large amount of mineral acid or caustic alkali. If the diazonium salts are isolated as tetrachlorozincates, the wastewater also contains considerable amounts of zinc ions. If all wastewaters are led into one collecting tank, partial neutralization takes place, which can be completed by the addition of a supension of calcium hydroxide in water, or powdered limestone. Many diazonium salts rapidly decompose under these conditions, usually into insoluble products that precipitate along with zinc hydroxide or carbonate. Residual products can be converted to insoluble azo dyes by adding wastewater containing naphtholate or other coupling components. The solids are concentrated by sedimentation, separated by filtration, and then incinerated or dumped on a certified landfill. The wastewater is discharged, sometimes after filtration through a sand filter, to a biological treatment facility to reduce the organic content still further.

Wastewater from the Sandmeyer reaction has to be treated to remove all traces of copper, preferably by adding sodium sulfide solution or by reductive treatment with, e.g., sodium borohydride. The precipitated copper sulfide or copper is isolated and recycled. The mother liquor from the cyanide replacement reaction contains cyanide. It is usually oxidized with chlorine, hypochlorite, or hydrogen peroxide to form cyanate. It may be also hydrolyzed to sodium formate and ammonia at a temperature of 200 °C [82].

Other solid wastes include filter residues from clarifications during diazotization processes, which mainly consist of activated carbon and filter aids such as diatomite. If the diazotization reactions are well controlled, only a small amount of undiazotized bases and insoluble decomposition products is present. These solid wastes can be incinerated like other organic waste products.

Table 1. Acute toxicity of some diazonium salts [87]

Diazonium salt *	Toxicity	
	LD_{50} (rat, oral), mg/kg	LC_0 (fish **), mg/L
2-Chlorobenzenediazonium tetrachlorozincate [*14263-92-4*]	1900	10 – 100
3-Chlorobenzenediazonium tetrafluoroborate [*456-39-3*]	1000	<10
5-Chloro-2-methoxybenzenediazonium tetrachlorozincate [*68025-25-2*]	1500	100 – 500
4-Chloro-2-nitrobenzenediazonium tetrachlorozincate [*14263-89-9*]	1600	10 – 100
4-Chloro-2-trifluormethylbenzenediazonium 1,5-naphthalenedisulfonate [*85222-98-6*]	3400	<10
2,5-Dichlorobenzenediazonium tetrachlorozincate [*14239-23-7*]	2200	<10
2,5-Dimethoxy-4-[(4-nitrophenylazo)]benzenediazonium tetrachlorozincate [*64071-86-9*]	3700	100 – 500
2-Methoxy-4-nitrobenzenediazonium 1,5-naphthalenedisulfonate [*49735-71-9*]	2500	
2-Methoxy-5-nitrobenzenediazonium tetrachlorozincate [*61919-18-4*]	1900	100 – 500
4-Methoxy-2-nitrobenzenediazonium tetrachlorozincate [*14239-24-8*]	2100	10 – 100
4-[(4-Methoxyphenyl)amino]benzenediazonium chloride [*101-69-9*]	200	
2-Methyl-4-[(2-methylphenyl)azo]benzenediazonium hydrogen sulfate [*101-89-3*]	2000	
2-Methyl-4-nitrobenzenediazonium tetrafluoborate [*455-90-3*]	1200	
2-Methyl-5-nitrobenzenediazonium 1,5-naphthalenedisulfonate [*49735-69-5*]	1800	10 – 100
2-Nitrobenzenediazonium tetrafluoroborate [*365-33-3*]	2000	
4-(Phenylamino)benzenediazonium chloride [*101-56-4*]	400	<10
3,3′-Dimethoxy-[1,1′-biphenyl]-4,4′-bis-(diazonium) tetrachlorozincate [*14263-94-6*]	1600	<10
3,3′-Dichlorobenzidinetetrazonium salt	>2000	70.7
2,4,5-Trichloranilinediazonium chloride	200 – 2000	11.9
2-Methoxy-4-nitroanilinediazonium chloride	200 – 2000	67.1
4-Chloro-2-nitroanilinediazonium chloride	200 – 2000	31.5

* As a commercial azoic diazo component: the amount of diazonium salt in a commercial diazo component is ca. 25 – 50 wt %, the rest being inorganic salts such as sodium sulfate and aluminum sulfate;
** *Lanciscus idus.*

6. Safety

Many diazo compounds are explosive, some even having the brisance of detonators. Therefore, a diazo product whith unknown explosive properties should be prepared in small quantities first and subjected to ignition and impact tests, as well as differential thermal analysis [83]. Before full-scale or pilot-plant production is initiated, an industrial safety investigation should be performed, e.g., following the guidelines of the Bundesamt für Materialprüfung (German Federal Office for Materials Testing) [84]. Commercial products must fulfill the criteria for non-explosive substances; otherwise, they can be marketed only under restrictive conditions. The same restrictions should be applied to intermediates.

In addition, flammability must not be overlooked. Although commercial products are usually self-extinguishing because of the presence of extenders, many intermediates, especially those containing nitro groups, can deflagrate.

Aqueous solutions of diazonium salts can decompose, but do not explode. They are protected against dangerous increase in temperature by the high specific heat and heat of vaporization of water. However, diazonium salt solutions in concentrated sulfuric acid, as formed in nitrosyl-diazotization, are a special case. Because of the low specific heat and the high boiling point of sulfuric acid, the heat of decomposition can raise the temperature sufficiently to trigger explosion [85].

7. Toxicology

Diazomethane is the most thoroughly investigated diazo compound with regard to toxicology. Acute poisoning follows a course similar to that of phosgene poisoning: a latent period is followed by severe difficulty in breathing and, in severe cases, by pulmonary edema. Animal trials have revealed carcinogenic properties; therefore, diazomethane is included under carcinogens Section 2 (former Section III A2) of the Technische Regeln für gefährliche Arbeitsstoffe; an MAK value is not quoted. For manufacture and use of diazomethane special rules must be observed [86]. For another aliphatic diazo compound, ethyl diazoacetate [*623-73-4*], the LD_{50} value for acute oral toxicity (rat) is 400 mg/kg.

Table 1 provides a survey of the acute toxicity of some aromatic diazonium salts used as azoic diazo components.

The acute oral toxicity of aromatic diazo compounds is somewhat greater: the LD_{50} values are 430 mg/kg for 3,3-dimethyl-1-phenyltriazene [*7227-91-0*], 224 mg/kg for 1,3-diphenyltriazene [*136-35-6*], and 63 mg/kg for 4-dimethylaminobenzene-*E*-diazosulfonate [*140-56-7*] [88].

1. Introduction

Aliphatic ω,ω'-dicarboxylic acids (or diacids) can be described by the following general formula:

$$HOOC-(CH_2)_n-COOH$$

According to IUPAC nomenclature, dicarboxylic acids are named by adding the suffix dioic acid to the name of the hydrocarbon with the same number of carbon atoms, e.g., nonanedioic acid for $n=7$. The older literature often uses another system based on the hydrocarbon for the $(CH_2)_n$ carbon segment and the suffix dicarboxylic acid, e.g., heptanedicarboxylic acid for $n=7$. However, trivial names are commonly used for the saturated linear aliphatic dicarboxylic acids from $n=0$ (oxalic acid) to $n=8$ (sebacic acid) and for the simple unsaturated aliphatic dicarboxylic acids; these names are generally derived from the natural substance in which the acid occurs or from which it was first isolated.

Aliphatic dicarboxylic acids are found in nature both as free acids and as salts. For example, malonic acid is present in small amounts in sugar beet and in the green parts of the wheat plant; oxalic acid occurs in many plants and in some minerals as the calcium salt. However, natural sources are no longer used to recover these acids.

The main industrial process employed for manufacturing dicarboxylic acids is the ring-opening oxidation of cyclic compounds.

Adipic acid is the most important dicarboxylic acid. Oxalic, malonic, suberic, azelaic, sebacic, and 1,12-dodecanedioic acids, as well as maleic and fumaric acids, are also manufactured on an industrial scale.

Dicarboxylic acids are important feedstocks in the manufacture of polyamides or of di- and polyesters. Esters produced by the reaction of

dicarboxylic acids with monofunctional alcohols serve as plasticizers or lubricants. In addition, dicarboxylic acids are used as intermediates in many organic syntheses.

2. Saturated Dicarboxylic Acids

The most important saturated aliphatic dicarboxylic acids are treated under separate keywords (see → Adipic Acid, → Malonic Acid and Derivatives, → Oxalic Acid).

2.1. Physical Properties

Dicarboxylic acids are colorless, odorless crystalline substances at room temperature. Table 1 lists the major physical properties of some saturated aliphatic dicarboxylic acids.

The lower dicarboxylic acids are stronger acids than the corresponding monocarboxylic ones. The first dissociation constant is considerably greater than the second. Density and dissociation constants decrease steadily with increasing chain length. By contrast, melting point and water solubility alternate: Dicarboxylic acids with an even number of carbon atoms have higher melting points than the next higher odd-numbered dicarboxylic acid. In the $n = 0-8$ range, dicarboxylic acids with an even number of carbon atoms are slightly soluble in water, while the next higher homologues with an odd number of carbon atoms are more readily soluble. As chain length increases, the influence of the hydrophilic carboxyl groups diminishes; from $n = 5$ (pimelic acid) onward, solubility in water decreases rapidly. The alternating solubility of dicarboxylic acids can be exploited to separate acid mixtures [1], [2]. Most dicarboxylic acids dissolve easily in lower alcohols; at room temperature, the lower dicarboxylic acids are practically insoluble in benzene and other aromatic solvents.

2.2. Chemical Properties

The chemical behavior of dicarboxylic acids is determined principally by the two carboxyl groups. The neighboring methylene groups are activated generally to only a minor degree; malonic acid derivatives (esters and nitriles) are an exception (→ Malonic Acid and Derivatives).

Thermal decomposition of dicarboxylic acids gives different products depending on the chain length. Acids with an even number of carbon atoms require higher decarboxylation temperatures than the next higher odd-numbered homologues; lower dicarboxylic acids decompose more easily than higher ones. To avoid undesired decomposition reactions, aliphatic dicarboxylic acids should only be distilled in vacuum. When heated above 190 °C, oxalic acid decomposes to carbon monoxide, carbon dioxide, and water. Malonic acid is decarboxylated to acetic acid at temperatures above 150 °C:

$$HOOC-CH_2-COOH \longrightarrow CH_3COOH + CO_2$$

When malonic acid is heated in the presence of P_2O_5 at ca. 150 °C, small amounts of carbon suboxide (C_3O_2) are also formed. Succinic and glutaric acids are converted into cyclic anhydrides on heating:

When the ammonium salt of succinic acid is distilled rapidly, succinimide is formed, with the release of water and ammonia.

Higher dicarboxylic acids from $n = 4$ (adipic acid) to $n = 6$ (suberic acid) split off carbon dioxide and water to form cyclic ketones:

The decomposition of still higher dicarboxylic acids leads to complex mixtures. With the exception of oxalic acid, dicarboxylic acids are resistant to oxidation. Oxalic acid is used as a reducing agent for both commercial and analytical purposes. Dicarboxylic acids react with dialcohols to form polyesters and with diamines to form polyamides. They also serve as starting materials for the production of the corresponding diamines. Reaction with monoalcohols yields esters. All of these reactions are commercially important. Several reactions with malonic and glutaric acids are of interest in organic syntheses: the Knoevenagel condensation,

Michael addition, and malonic ester synthesis (→ Malonic Acid and Derivatives) [3], [4].

Succinic acid ester reacts with aldehydes or ketones in the presence of sodium ethoxide or potassium *tert*-butoxide to form alkylidenesuccinic acid monoesters (Stobbe condensation). These can subsequently be converted into monocarboxylic acids by hydrolysis, decarboxylation, and hydrogenation [5]:

Cyclic ketones are obtained from C_6–C_8 dicarboxylic acid esters and sodium methoxide (Dieckmann reaction) [6]. Esters of adipic, pimelic, and suberic acids can be converted in good yields; esters of higher dicarboxylic acids cannot be cyclized by this method.

Acyloin condensation with metallic sodium gives cyclic acyloins; this method is particularly suitable for synthesis of large rings [7]:

Detailed summaries of reactions with dicarboxylic acids can be found in [8].

2.3. Production

A number of straight-chain aliphatic dicarboxylic acids and their derivatives occur in nature. However, isolation from natural substances has no commercial significance. Although many syntheses for the production of aliphatic dicarboxylic acids are known, only a few have found industrial application. This is due partly to the shortage of raw materials.

The most important processes for the manufacture of saturated aliphatic dicarboxylic acids are the following:

1) Oxidative cleavage of cyclic compounds (e.g., adipic acid from cyclohexane, 1,12-dodecanedioic acid from 1,5,9-cyclododecatriene)
2) Oxidative cleavage of unsaturated monocarboxylic acids (e.g., azelaic acid from oleic acid)
3) Alkaline cleavage of substituted monocarboxylic acids (e.g., sebacic acid from ricinoleic acid)
4) Hydrogenation of unsaturated dicarboxylic acids (e.g., succinic acid from maleic acid)
5) Oxidation of ω,ω'-diols (e.g., pimelic acid from 1,7-heptanediol)
6) Carbonylation reactions (e.g., suberic acid from 1,6-hexanediol)

Some special syntheses are also of interest. The following sections treat the most important manufacturing processes, which can be subdivided into degradative methods, processes in which the carbon structure is maintained, and synthetic methods starting from smaller units.

2.3.1. Degradative Methods

Ozonolysis of Oleic Acid. Ozonolysis of oleic acid [*112-80-1*] followed by oxidative cleavage gives pelargonic acid [*112-05-0*] and azelaic acid [9]:

Figure 1 shows a commercial process for the production of azelaic acid from oleic acid.

Oleic acid is cleaved by ozonolysis (O_3 concentration in the air: 1.0 vol %) at 20 – 40 °C in pelargonic acid and water. The alkene residence time is about 10 min. The ozonide is then cleaved with oxygen at 70 – 110 °C. Pelargonic and azelaic acids are separated from higher boiling compounds by subsequent distillation. Azelaic acid is subjected to extraction to remove monocarboxylic acids; distillation of the extractant finally yields pure acid.

Figure 1. Manufacture of azelaic acid by ozonolysis of oleic acid
a) Ozone generator; b) Ozone absorber; c) Reactor; d) Distillation column; e) Extraction column; f) Distillation of the extractant; g) Flaking

Cleavage of Ricinoleic Acid. Alkaline cleavage of ricinoleic acid [*141-22-0*] (12-hydroxy-9-octadecenoic acid) under pressure and at high temperature leads to the formation of sodium sebacate and 2-octanol [10]:

$$CH_3-(CH_2)_5-CH(OH)-CH_2-CH=CH-(CH_2)_7-COOH \xrightarrow{NaOH} NaOOC-(CH_2)_8-COONa + CH_3-(CH_2)_5-CH(OH)-CH_3$$

In industry, castor oil [*8001-79-4*], which contains about 87 % ricinoleic acid, is normally used instead of the pure acid.

Oxidation with N_2O_4. Oxidative degradation of monocarboxylic acids generally produces dicarboxylic acid mixtures; the composition of the reaction products shifts toward the higher dicarboxylic acids as the chain length of the monocarboxylic acids increases. Oxidation of stearic acid [*57-11-4*] with N_2O_4 yields a mixture consisting mainly of sebacic and caprylic [*124-07-2*] acids. In the same way, palmitic acid [*57-10-3*] can be oxidized with nitric acid – N_2O_4 to form suberic acid [11].

Commercial production of adipic acid from cyclohexanol – cyclohexanone yields two major byproducts, succinic and glutaric acids, which can be separated easily (→ Adipic Acid, Chap. 5.).

Oxidation of Hydrocarbons. Oxidative degradation of hydrocarbons is also a common manufacturing process. The best-known example is the oxidation of benzene to maleic acid by means of vanadium pentoxide catalysts (→ Maleic and Fumaric Acids).

2.3.2. Processes Maintaining the Carbon Structure

Cleavage of Cyclic Compounds. Many processes for the manufacture of dicarboxylic acids by oxidative cleavage of cyclic compounds are commercially significant; however, the oxidation of cyclohexane via cyclohexanol – cyclohexanone is the most important (→ Adipic Acid). Similar processes are employed to convert cyclopentanol – cyclopentanone to glutaric acid, cycloheptanone to pimelic acid, and cyclododecanol – cyclododecanone to 1,12-dodecanedioic acid [12]. Figure 2 shows a process for the manufacture of 1,12-dodecanedioic acid from cyclododecanol – cyclododecanone [13].

The oxidation is carried out in a stirred reactor (b) fed continuously with nitric acid and cyclododecanol – cyclododecanone; ammonium vanadate is used as a catalyst. The nitric oxides formed during oxidation are recycled via the

condenser (d) and cooler (e). The reaction slurry passes to the postreaction stage and then to the crystallizer (g), in which most of the acid crystallizes. The solids are filtered off and the mother liquor is recycled to the reactor. In industrial-scale processes, selectivities toward the acid of about 90 % are achieved.

Figure 2. Manufacture of 1,12-dodecanedioic acid from cyclododecanol – cyclododecanone
a) Scrubber; b) Reactor; c) Downstream reactor; d) Condenser; e) Cooler; f) Separator; g) Crystallizer; h) Filter

Cyclic ethers can also be used as starting materials. Thus, pimelic acid is obtained from potassium tetrahydrofurylpropionate [14] or from hydroxycyclohexanoic acid [15]. Hydrolysis of dihydropyran produces 5-hydroxypentanal, which is converted to glutaric acid by subsequent oxidation with nitric acid [16].

Ozonolysis of Cyclic Olefins. Cyclic olefins can be converted to dicarboxylic acids by ozonolysis and subsequent oxidative cleavage. For example, 1,12-dodecanedioic acid can be obtained by ozonolysis of cyclododecene (see Section 2.4.9) [17].

Oxidation of Bifunctional Compounds. Dicarboxylic acids can be produced by oxidation of bifunctional compounds with HNO_3 in the presence of ammonium vanadate, with N_2O_4, or with oxygen in the presence of palladium on carbon. Diols are preferred as bifunctional starting materials. Well-known examples of this process are the syntheses of pimelic acid from 1,7-heptanediol and of succinic acid from 1,4-butanediol [18].

Nitrile Hydrolysis. Saponification of dinitriles also yields dicarboxylic acids. Thus, glutaric acid can be produced from glutarodinitrile, which is obtained by the reaction of 1,3-dihalopropane with sodium cyanide. Saponification of the nitrile group can take place concurrently with oxidation of a carbonyl group; e.g., 4-cyano-2,2-dimethylbutanal, obtained by the addition of isobutanal to acrylonitrile, gives 2,2-dimethylglutaric acid [19].

Hydrogenation. Hydrogenation of unsaturated dicarboxylic acids or their anhydrides produces good yields of the corresponding saturated compounds. Succinic acid is obtained by this method from maleic acid or maleic anhydride [20].

Fermentation. Numerous alkane-based fermentation processes have been described for the manufacture of dicarboxylic acids [21]. However, these biotechnical processes have not yet become standard commercial practice.

2.3.3. Syntheses from Smaller Units

The main addition reactions leading to dicarboxylic acids are variants of carbonylation. Diolefins, dialcohols, and unsaturated monocarboxylic acids are used as starting materials

[22]. Reppe carbonylation of 1,6-hexanediol produces suberic acid; C_{19} dicarboxylic acids are obtained from oleic acid [23].

The dimerization of monomethyl adipate to sebacic acid is an electrochemical process which has achieved commercial significance. Figure 3 illustrates this process [24].
The reaction takes place in three stages:
Esterification:

$$\mathrm{HOOC{-}(CH_2)_4{-}COOH + CH_3OH \longrightarrow HOOC{-}(CH_2)_4{-}COOCH_3 + H_2O}$$

Electrolysis:

$$\mathrm{{}^{-}OOC{-}(CH_2)_4{-}COOCH_3 - e^- \longrightarrow 1/2\,CH_3OOC{-}(CH_2)_8{-}COOCH_3 + CO_2}$$

$$\mathrm{H^+ + e^- \longrightarrow 1/2\,H_2}$$

Hydrolysis:

$$\mathrm{CH_3OOC{-}(CH_2)_8{-}COOCH_3 + 2\,H_2O \longrightarrow HOOC{-}(CH_2)_8{-}COOH + 2\,CH_3OH}$$

In the first stage, adipic acid reacts with methanol at 80 °C to form monomethyl adipate. Ion exchangers containing sulfonic acid groups are used as catalysts and also prevent the formation of byproducts such as cyclopentanone. The monomethyl adipate is separated by distillation.

In the second stage, the potassium salt of monomethyl adipate is dimerized electrolytically either continuously or batchwise. The electrolyzer is equipped with bipolar electrodes. Electrolysis takes place at 50 – 60 °C. Aqueous methanol is used as solvent, the H_2O concentration being between 0.15 and 0.30 %. The resulting dimethyl sebacate solution is distilled, and unreacted potassium methyl adipate is returned to the electrolysis process. Dimethyl sebacate is purified by distillation.

In the third stage, dimethyl sebacate is hydrolyzed at 160 – 180 °C and a pressure of about 0.9 MPa (9 bar). Methanol is removed, and the crude sebacic acid is treated with activated carbon and then dried.

The Wurtz synthesis can also be used [25]:

$$\mathrm{2\,Cl{-}CH_2{-}COOR + 2\,Na \longrightarrow ROOC{-}(CH_2)_2{-}COOR + 2\,NaCl \xrightarrow{H_2O} HOOC{-}(CH_2)_2{-}COOH}$$

The reactivity of the methylene group in malonic ester is exploited in many dicarboxylic acid syntheses (malonic ester synthesis; → Malonic Acid and Derivatives).

The Stetter dicarboxylic acid synthesis is another important process [26]:

Long-chain dicarboxylic acids can be prepared in the following manner [27]:

Many processes used to manufacture monocarboxylic acids are also suitable for the synthesis of dicarboxylic acids. This field has been reviewed extensively [28] (→ Carboxylic Acids, Aliphatic).

2.4. Individual Saturated Dicarboxylic Acids

Dicarboxylic acids are used mainly as intermediates in the manufacture of esters and polyamides. Esters derived from monofunctional alcohols serve as plasticizers or lubricants. Polyesters are obtained by reaction with dialcohols. In addition, dicarboxylic acids are employed in the manufacture of hydraulic fluids, agricultural chemicals, pharmaceuticals, dyes, complexing agents for heavy-metal salts, and lubricant additives (as metal salts).

2.4.1. Succinic Acid

Succinic acid is found in amber, in numerous plants (e.g., algae, lichens, rhubarb, and tomatoes), and in many lignites.

Figure 3. Manufacture of sebacic acid by electrochemical dimerization of monomethyl adipate
a) Mixing tank; b) Reaction column; c) Methanol stripper; d) Water stripper; e) Dimethyl adipate stripper; f) Adipic acid cutting column; g) Electrolyzer; h) Electrolyte tank; i) Decanter; J) Distillation column; k) Reactor; l) Mixing tank; m) Filter; n) Dehydrator; o) Prill tower

Production. A large number of syntheses are used to manufacture succinic acid. Hydrogenation of maleic acid, maleic anhydride, or fumaric acid produces good yields of succinic acid; the standard catalysts are Raney nickel [20], Cu, NiO, or CuZnCr [29], $Pd-Al_2O_3$ [30], $Pd-CaCO_3$ [31], or Ni – diatomite [32]. 1,4-Butanediol can be oxidized to succinic acid in several ways: (1) with O_2 in an aqueous solution of an alkaline-earth hydroxide at 90 – 110 °C in the presence of Pd – C; (2) by ozonolysis in aqueous acetic acid; or (3) by reaction with N_2O_4 at low temperature [18]. Succinic acid or its esters are also obtained by Reppe carbonylation of ethylene glycol, catalyzed with $RhCl_3$ – pentachlorothiophenol [33]; Pd-catalyzed methoxycarbonylation of ethylene [34]; and carbonylation of acetylene, acrylic acid, dioxane, or β-propiolactone [35], [36] (→ Carbonylation).

Acid mixtures containing succinic acid are obtained in various oxidation processes. Examples include the manufacture of adipic acid [2], [37–39] (→ Adipic Acid, Chap. 4.1.); the oxidation of enanthic acid [40]; and the ozonolysis of palmitic acid [41].

Succinic acid can also be obtained by phase-transfer-catalyzed reaction of 2-haloacetates [42], electrolytic dimerization of bromoacetic acid or ester [43], oxidation of 3-cyanopropanal [44], and fermentation of *n*-alkanes [45].

Uses. Succinic acid is used as a starting material in the manufacture of alkyd resins, dyes, pharmaceuticals, and pesticides. Reaction with glycols gives polyesters; esters formed by reaction with monoalcohols are important plasticizers and lubricants.

2.4.2. Glutaric Acid

Glutaric acid occurs in washings from fleece and, together with malonic acid, in the juice of unripened sugar beet.

Production. Glutaric acid is obtained from cyclopentane by oxidation with oxygen and cobalt (III) catalysts [46], [47] or by ozonolysis [48]; and from cyclopentanol – cyclopentanone by oxidation with oxygen and $Co(CH_3CO_2)_2$, with potassium peroxide in benzene, or with N_2O_4 or nitric acid [12], [49–51]. Like succinic acid, glutaric acid is formed as a byproduct during oxidation of cyclohexanol – cyclohexanone (→ Adipic Acid).

Other production methods include reaction of malonic ester with acrylic acid ester [52], [53], carbonylation of γ-butyrolactone [22], oxidation of 1,5-pentanediol with N_2O_4 [18], and oxidative cleavage of γ-caprolactone [54].

Uses. The applications of glutaric acid, e.g., as an intermediate, are limited. Its use as a starting material in the manufacture of maleic acid has no commercial importance.

2.4.3. Dimethylglutaric Acids

2,2-Dimethylglutaric acid is manufactured from dimethyl-γ-butyrolactone by carbonylation using $HF-SbF_5$ as a catalyst or by reaction with formic acid in stronger acids such as $H_2SO_4-SO_3$ [55], [56]. 4-Cyano-2,2-dimethylbutanal, which is obtained by addition of isobutanal to acrylonitrile, can be converted to the acid by oxidation of the formyl group and subsequent hydrolysis of the nitrile group [19], [57].

2,2-Dimethylglutaric acid is used in the manufacture of diglycidyl esters (for coating materials) [58], pyrethroids (for insecticides and acaricides) [59], and antibiotics [60].

3,3-Dimethylglutaric acid [*4839-46-7*] is manufactured from isophorone by oxidation with H_2O_2 in the presence of concentrated sulfuric acid or by ozonolysis in methanolic solution and subsequent oxidation with H_2O_2 [61]. This acid is used in the manufacture of pesticides and lubricating oil additives.

2.4.4. Trimethyladipic Acid

Commercial trimethyladipic acid is a mixture of ca. 40 % 2,2,4-trimethyladipic acid and 60 % 2,4,4-trimethyladipic acid.

Production. Trimethyladipic acid is manufactured by oxidative cleavage of 3,3,5-trimethylcyclohexanol [*116-02-9*] (produced from acetone) with 65 % nitric acid at 50 °C [62]. To separate the short-chain dicarboxylic acids, the mixture is heated to 180 – 250 °C and the cyclic anhydrides formed are distilled off [63].

Uses. Trimethyladipic acid is used in the production of synthetic lubricating oils [64], polyesters [65], and polyamides [65], and in the modification of terephthalic acid esters [66].

2.4.5. Pimelic Acid

Pimelic acid is an oxidation product of fats.

Production. Pimelic acid can be manufactured with good selectivity by oxidation of cycloheptanone [*502-42-1*] (suberone) with N_2O_4 [12]. It is also obtained in a mixture with other dicarboxylic acids by oxidative cleavage of palmitic acid [41]. Other manufacturing processes include oxidation of 1,7-heptanediol [67], carbonylation of ε-caprolactone [22], and acid cleavage of tetrahydrosalicylic acid with potassium hydroxide at 300 °C under pressure [15].

Uses. Pimelic acid has slight significance as a starting material in the manufacture of polyesters and polyamides.

2.4.6. Suberic Acid

Suberic acid is formed from the action of nitric acid on cork.

Production. Suberic acid is manufactured by oxidation of cyclooctene with ozone – oxygen [48], [68] or with ozone – H_2O_2 [69]. The acid is formed together with other dicarboxylic acids during ozonolysis of palmitic acid [41] as well as during cleavage of ricinoleic acid with nitric acid [70]. Other manufacturing processes include oxidation of cyclooctanol – cyclooctanone with N_2O_4 or HNO_3 [12], [71], carbonylation of 1,6-hexanediol [72], and oxidative cleavage of 2-(cyclohexanon-2-yl)acetic acid ethyl ester [26].

Uses. Suberic acid has been used in the manufacture of mono- and diesters as well as polyamides. Nylon 6,8 is obtained by reaction of suberic acid with hexamethylenediamine,

and nylon 8,8 by reaction with octamethylenediamine. Polyamides of suberic acid with diamines such as 1,3-bis(aminomethyl)benzene, 1,4(bisaminomethyl)cyclohexane, and bis(4-aminocyclohexyl)methane are also of commercial interest. Esters of suberic acid with mono- and bifunctional alcohols are used as lubricants.

2.4.7. Azelaic Acid

Azelaic acid occurs in many natural substances containing long-chain fatty acids.

Production. Azelaic acid is obtained by oxidative cleavage of oleic acid with oxidants such as RuO_4 [73]; $Cl_2 - RuO_2$ or $Cl_2 - RuCl_2$ [74], [75]; $KMnO_4$ [76]; $NaOCl - RuO_4 - OsO_4$ [77]; and HNO_3 [78]. The industrially most important process is the ozonolysis of oleic acid (see Section 2.3.1) [9], [79], [80].

Other means of synthesizing azelaic acid include carbonylation of 1,5-cyclooctadiene [81], oxidation of 1,9-nonanedial with oxygen [82], oxidative cleavage of 2-cyanoethylcyclohexanone [83], and fermentation of pelargonic acid [84]. A mixture of azelaic and other dicarboxylic acids is obtained during ozonolysis of palmitic acid [41].

Uses. Monoesters of azelaic acid with 2-ethylhexanol are used as plasticizers. Mono- and diesters with other alcohols act as hydraulic fluids and lubricating oils; their metal salts are recommended as lubricating oil additives. Reaction with hexamethylenediamine leads to nylon 6,9, which is used as extruded film for food packaging, as a coating for wire, and in the electronics and automobile industries. Unsaturated polyesters are employed as resins, laminates, and adhesives.

2.4.8. Sebacic Acid

Production. The most important processes for manufacturing sebacic acid are alkaline cleavage of ricinoleic acid (see Section 2.3.1) [85–88] and electrolytic dimerization of monomethyl adipate (see Section 2.3.3) [89–91]. 2-Octanol is formed as a byproduct during ricinoleic acid cleavage. Other methods used to manufacture sebacic acid are oxidation of stearic acid by N_2O_4 [11], oxidation of 1,10-decanediol [18], and various fermentation processes [21], [92]. A mixture of sebacic acid and other dicarboxylic acids is formed during ozonolysis of palmitic acid [41]. Processes for purifying sebacic acid are described in [93–95].

The C_{10} dicarboxylic acid mixture obtained by dimerization of butadiene and subsequent reaction with CO_2 is called isosebacic acid; it consists of ca. 75 % 2-ethylsuberic acid, 15 % diethyladipic acid, and 10 % sebacic acid. Because of the varying composition of different production batches, this mixture has not been able to gain a foothold in the market.

Uses. The polyamide nylon 6,10 obtained by reaction of sebacic acid with hexamethylenediamine no longer has great industrial significance. The sebacates of various oxo and straight-chain alcohols are important plasticizers. Their main characteristics are high migration resistance and good low-temperature resistance. The esters are also used as components of lubricating oils and as diluents; because of their low toxicity they are important components of packaging films. Sebacic acid-based alkyd resins are characterized by marked flexibility.

2.4.9. 1,12-Dodecanedioic Acid

Over the past few years, 1,12-dodecanedioic acid has achieved industrial importance.

Production. The starting compound for industrial-scale production of 1,12-dodecanedioic acid is 1,5,9-cyclododecatriene (CDT), which is obtained by trimerization of butadiene (→ Cyclododecatriene, Cyclooctadiene, and 4-Vinylcyclohexene). Cyclododecatriene can react to form the acid by two different processes. In a three-stage reaction sequence, 1,5,9-cyclododecatriene is first hydrogenated to cyclododecane on nickel catalysts; cyclododecane is then oxidized with oxygen or air to a cyclododecanol – cyclododecanone mixture; and this mixture is finally oxidized with nitric acid to 1,12-dodecanedioic acid (→ Cyclododecanol, Cyclododecanone, and Laurolactam) [96–100].

The second route consists of partial hydrogenation of 1,5,9-cyclododecatriene to cyclododecene and subsequent oxidative ozonolytic cleavage to the acid [101–103]; ozonolysis of cyclododecanol has also been described [17].

Other manufacturing processes such as the fermentation of *n*-dodecane [21], [104], [105] and the oxidation of analogous mono- and diformyl compounds [106] have no industrial importance. Processes for purifying the acid have been described [107–110].

Uses. 1,12-Dodecanedioic acid is used mainly in manufacturing polyamides and polyesters. Reaction with hexamethylenediamine gives nylon 6,12; reaction with *trans,trans*-bis-(4-aminocyclohexyl)methane yields the polyamide known as Qiana. 1,12-Dodecanedioic acid is also used for the manufacture of lubricating oils and plasticizers.

2.4.10. 1,13-Tridecanedioic Acid (Brassylic Acid)

Production. The most important raw material for the production of brassylic acid is erucic acid [*112-86-7*] (*cis*-13-docosenoic acid), which occurs in large quantities in the seed oil of rape, mustard, wallflower, and cress. Yields of 82 – 92 % are obtained by ozonolysis of erucic acid in acetic acid and subsequent oxidation with oxygen [111], [112]. The byproduct, pelargonic acid, can be separated easily. Oxidative cleavage of erucic acid by reaction with nitric acid is also possible [78].

$$CH_3-(CH_2)_7-CH{=}CH-(CH_2)_{11}-COOH \longrightarrow$$
$$CH_3-(CH_2)_7-COOH + HOOC-(CH_2)_{11}-COOH$$

Fermentation of *n*-tridecane has been investigated over the past few years, especially in Japan [113–117]; purification of the resulting acid is described in [118–121].

Uses. Brassylic acid is used in the manufacture of polyamides (nylon 13,13) and esters which are employed as low-temperature plasticizers for poly(vinyl chloride) (PVC) and as lubricant components. It is also a starting material for synthetic musk.

2.4.11. C_{19} Dicarboxylic Acids

Production. The composition of C_{19} dicarboxylic acid mixtures depends on the manufacturing process. Three processes, based on oleic acid or oleic acid esters, are used industrially: (1) Reppe carbonylation catalyzed by $Ni(CO)_4$ or metal complexes such as $PdCl_2$ – triphenylphosphine; (2) Koch reaction in concentrated sulfuric acid at 10 – 20 °C [23], [122], [123] or with HF catalysis at 30 °C [124]; and (3) hydroformylation. Hydroformylation gives a mixture of isomeric formylstearates, which are subsequently oxidized with air or oxygen. Oxidation takes place in an aqueous emulsion at 20 – 25 °C in the presence of calcium acetate or manganese naphthenate catalyst [125], [126]. Potassium permanganate [127–129] or potassium dichromate [128], [129] can also be used as the oxidizing agent.

Uses. Esters of C_{19} dicarboxylic acids are used as plasticizers for PVC. The esterification rate of the terminal carboxyl group is considerably higher than that of the central group. This allows selective synthesis of mixed esters.

The C_{19} dicarboxylic acids are also used as starting materials in the production of polyamides, epoxy resins, unsaturated polyester resins, lubricants, and adhesives.

3. Unsaturated Dicarboxylic Acids

The most important derivative of unsaturated dicarboxylic acids is maleic anhydride (→ Maleic and Fumaric Acids). Unsaturated C_{36} dicarboxylic acids containing cyclic structures, which are known as dimer acids, also have some industrial significance.

3.1. Physical Properties

Table 2 lists the most important physical properties of some unsaturated aliphatic dicarboxylic

acids. The lower members of the series are colorless, crystalline substances at room temperature; the dimer acids, which are commercially available as isomeric mixtures, are viscous liquids at 25 °C. Melting point, solubility in water, and dissociation constants of the lower homologues are influenced by configuration. For example, the melting points of fumaric and mesaconic acid (trans) are considerably higher than those of the cis isomers maleic and citraconic acid, respectively; the trans isomers are also much less water soluble and less acidic. An indication of the higher stability of the trans form is the higher heat of combustion of maleic acid compared with fumaric acid.

3.2. Chemical Properties

The chemical behavior of unsaturated aliphatic dicarboxylic acids is determined primarily by the two carboxyl groups (see Section 2.2) and the olefinic double bond. Reactions of the carboxyl groups can also be influenced by the olefinic bond. For example, when maleic or citraconic acid is heated above 100 °C, water is split off, and maleic or citraconic anhydride is obtained (→ Maleic and Fumaric Acids). Fumaric acid, however, forms no anhydride; above 230 °C, decomposition occurs and maleic anhydride, water, and an appreciable amount of residue are formed.

Addition of halogen to the carbon – carbon double bond yields dihalodicarboxylic acids; reaction with ozone gives formylcarboxylic acids; and hydroxydicarboxylic acids are formed by addition of water. Catalytic hydrogenation leads to saturated dicarboxylic acids; the cis isomers generally react much more quickly than the trans isomers.

The Diels – Alder reaction of maleic anhydride with conjugated dienes is used both industrially and in preparative organic chemistry [130]; for example, tetrahydrophthalic anhydride is formed by reaction with butadiene:

Comprehensive information on reactions with unsaturated dicarboxylic acids can be found in [131].

3.3. Production

Only a few processes are used industrially for the production of unsaturated dicarboxylic acids:

1) Oxidation of hydrocarbons (maleic anhydride from benzene and C_4 hydrocarbons such as *n*-butane and *n*-butene; see → Maleic and Fumaric Acids)
2) Diels – Alder reaction of unsaturated acids (dimer acids from oleic or linoleic acid; see Section 3.4.2)
3) Fermentation (itaconic acid)

3.4. Individual Unsaturated Dicarboxylic Acids

Unsaturated dicarboxylic acids are used mainly to manufacture unsaturated polyester resins, copolymers, or polyamides, and as intermediates in the synthesis of herbicides, insecticides, fungicides, surfactants, lubricants, and plasticizers.

Maleic anhydride is also employed as a starting material for the manufacture of DL-tartaric acid, DL-malic acid, glyoxylic acid, and tetrahydrophthalic anhydride, as well as γ-butyrolactone, 1,4-butanediol, and tetrahydrofuran.

3.4.1. Itaconic Acid

Itaconic acid (2-methylenebutanedioic acid) is soluble in water; moderately soluble in chloroform, benzene, and ligroin; and slightly soluble in ether. When distilled at normal pressure, itaconic acid or itaconic anhydride yields citraconic anhydride.

Production. Itaconic acid is produced by fermentation [132–138]. A mixture of itaconic acid, citraconic acid, and citraconic anhydride is obtained by reaction of succinic anhydride with formaldehyde at 200 – 500 °C in the presence of alkali or alkaline-earth hydroxides [139]; $SiO_2 - Al_2O_3$ or $SiO_2 - MgO$ can also be used

Table 2. Physical properties of unsaturated dicarboxylic acids

IUPAC name	Common name	CAS registry number	Formula	M_r	*mp*, °C	ϱ at 20 °C, g/cm³	Solubility in H_2O, wt %	Ionization constants K_1	K_2
cis-Butenedioic acid	maleic acid	[*110-16-7*]		116.07	143.5	1.590	78.9 (25 °C)	1.14×10^{-2}	5.95×10^{-7}
trans-Butenedioic acid	fumaric acid	[*110-17-8*]		116.07	296–298	1.635 (25 °C)	0.428 (15.5 °C)	9.57×10^{-4}	4.13×10^{-5}
2-Methyl-*cis*-butenedioic acid	citraconic acid	[*498-23-7*]		130.10	93	1.617		1.10×10^{-3}	1.0×10^{-6}
2-Methyl-*trans*-butenedioic acid	mesaconic acid	[*498-24-8*]		130.10	204.5	1.466	2.7 (18 °C)	4.78×10^{-4}	1.86×10^{-5}
2-Methylenebutanedioic acid	itaconic acid	[*97-65-4*]		130.10	175	1.632	8.3	1.5×10^{-4}	2.2×10^{-6}
2-Methylenepentanedioic acid	2-methylene-glutaric acid	[*3621-79-2*]		144.12	132–133				
2,4-Hexadienedioic acid	muconic acid (cis–cis)	[*3588-17-8*]		142.11	194–195				

as catalysts [140]. Other methods involve carbonylation of propargyl chloride with metal carbonyl catalysts [141] and thermal decomposition of citric acid.

Uses. Itaconic acid can be used as a comonomer and in the separation of triorganophosphine mixtures [142].

3.4.2. Dimer Acids

The only higher dicarboxylic acids of commercial importance are unsaturated cyclic C_{36} dicarboxylic acids known as dimer acids. The main difference among various standard proprietary products is the content of trimer compounds; the ratio of dimer to trimer acids can vary from 36 : 1 to about 0.7 : 1 [143]. The composition of dimer acids depends to a large degree on the feed materials and the manufacturing process.

Production. Dimer acids are produced by intermolecular condensation of unsaturated C_{18} carboxylic acids or their esters. Tall oil fatty acids are the main feed materials, but oleic and linoleic acids can also be used. The reaction is conducted preferably in the presence of special aluminum silicates (montmorillonites) at 190 – 240 °C; thermal dimerization at 270 – 290 °C is also possible [144–147]. Numerous catalyst modifications such as addition of alkali, amines, or sulfonic acid halides are described in the literature. A summary of the manufacturing processes for dimer acids can be found in [151–153]. Diels – Alder and free-radical reactions have been suggested as mechanisms for the thermal dimerization [148]; when aluminum silicates are used, ionic intermediates may be formed. Commercial processes yield mixtures of dimer acids, higher polycarboxylic acids, and various isomeric monomer acids, which are separated by distillation using film evaporators. After removal of the monomer acid fraction and the polycarboxylic acids, the remaining acids can be separated by further distillation into dimer and trimer acids. Figure 4 shows some dimer acids found in commercial mixtures. Investigations of the structures of dimer acids can be found in [149], [150].

Uses. The dimer acids produced on an industrial scale are used in the manufacture of polyamides, polyesters, epoxy resins, lubricants, plasticizers, and pesticides [154–157].

Figure 4. Dimer acids found in commercial mixtures

4. Quality Specifications and Analysis

Quality control of dicarboxylic acids covers the determination of content, melting point, color, traces of heavy metals, and solubility in water or other solvents. High purity is generally demanded of dicarboxylic acids.

The content of dicarboxylic acids is usually determined by acidimetric titration. Specific regulations exist for properties; for regulations concerning dimer acids, see [158, 159]. Specifications may include condition, color, content, and ash. Melting point, density, refractive index, water content, steam pressure, specific heat, dissociation constants, and solubility in water and other solvents are also often determined.

The most important qualitative or quantitative analytical method used industrially is gas chromatography. Dicarboxylic acids are first converted into their esters (preferably methyl esters) because free acids generally undergo undesirable secondary reactions during chromatography. Both packed columns and capillary columns with stationary liquids of different polarities are used. Calcined kieselguhr is the most common carrier material. Other chromatographic methods such as HPLC, paper and thin-layer chromatography, and gel chromatography are also widely employed.

Alkalimetric titration is commonly used to monitor the different production steps and to

identify pure dicarboxylic acids or their mixtures. In the absence of other reducing agents, oxalic acid is determined by titration with potassium permanganate. Crystalline derivatives such as phenacyl esters and amides are particularly suitable for chemical determination of dicarboxylic acids.

With infrared spectroscopy, dicarboxylic acids can be detected by the intense carbonyl stretching frequency in the range of $1650-1740\,cm^{-1}$. In the ^{1}H-NMR spectrum, the hydroxyl proton signals can be found at $\delta = 10-13$ ppm; the signals for the methylene groups of malonic and succinic acids are around 3.4 and 2.6 ppm, respectively. In the ^{13}C-NMR spectrum, the absorption range of the carboxyl carbon atom is around $\delta = 160-180$ ppm.

For further details on analysis, see [158], [160].

5. Storage, Transportation, and Handling

At room temperature, straight-chain dicarboxylic acids are solid compounds that are delivered and stored as crystals or – particularly if a melt or distillation is used to recover the pure substance – as flakes.

Dicarboxylic acids are stored and transported in drums made of plastic-coated steel, stainless steel, or aluminum. Polyethylene-lined paper sacks are also used. These acids are hygroscopic and should be stored in cool, dry rooms to avoid clumping. Shipping regulations and hazard classification for dicarboxylic acids depend on the specific properties of the compounds such as flash point, decomposition temperature, water solubility, toxicity, and ignition temperature.

Aliphatic dicarboxylic acids are local irritants, especially to the mucous membranes; this effect decreases with increasing chain length. Oxalic acid is absorbed readily by the outer layers of the skin and can upset the body's calcium balance through the formation of calcium oxalate. Therefore, gloves and safety glasses must be worn when dicarboxylic acids are handled. To avoid dust that can damage health, dicarboxylic acids are normally supplied in the form of flakes or laminated moldings.

Waste gases from dicarboxylic acid production facilities are generally drawn off at a central point and fed into a combustion chamber. The wastewater is subjected to chemical and biological treatment.

1. Introduction

Dimethyl ether [*115-10-6*], C_2H_6O, is the simplest aliphatic ether.

CH_3–O–CH_3

For a long time it was obtained on an industrial scale as a byproduct in the high-pressure production of methanol. Recently the high-pressure methanol plants have been almost completely replaced by low-pressure plants; this has led to the erection of special plants for the synthesis of dimethyl ether. The production of dimethyl ether in Western Europe is approx. 50 000 t per year. Dimethyl ether is industrially important as the starting material in the production of the methylating agent dimethyl sulfate and is used as an aerosol propellant.

2. Properties

Dimethyl ether (DME, methoxymethane), M_r 46.07, is a colorless, almost odorless gas at room temperature and atmospheric pressure and has the following physical properties:

M_r	46.07
bp at 0.1 MPa	− 24.8 °C
mp	− 141 °C
Critical pressure	5.28 MPa (52.84 bar) [1]
Critical temperature	400.29 K [1] (127.1 °C)
Critical density	269.9 kg/m^3 [1]
Heat of combustion (gas)	31.75 MJ/kg
Heat of formation	−183 kJ/mol
Specific heat capacity (at −24 °C)	2.26 kJ kg^{-1} K^{-1}
Heat of vaporization (at −20 °C)	410.2 kJ/kg
Autoignition temperature	235 °C [2]
Explosive limits	3.0 – 17 vol % in air
Flash point	− 41 °C
Relative density (gaseous, air = 1)	1.59
Density	
(at 20 °C)	668.3 kg/m^3 [2]
(at 50 °C)	615.0 kg/m^3 [2]
Solubility in water	
(at 20 °C, 1 bar)	5.7 wt % [2]
(at 20 °C, 4.8 bar)	36 wt % [2]
Surface tension (liquid)	0.0125 N/m [2]
Viscosity	
gaseous	0.0091 mPa · s [2]
liquid	0.11 mPa · s

Density of liquid dimethyl ether [2]:

t, °C	10	20	30	40	50	60	70	80
ϱ, kg/m^3	682	666	649	631	612	593	573	552

Vapor pressure [2]:

t, °C	−20	−10	0	10	20	50
p, MPa						
measured	0.124	0.184	0.266	0.375	0.512	1.149
calculated	0.114	0.185	0.267	0.374	0.512	1.152

Dimethyl ether is miscible with most polar and nonpolar organic solvents. It is also partly miscible with water (76 g in 1 L of water at 18 °C). In addition, numerous polar and nonpolar substances readily dissolve in dimethyl ether.

Chemical Properties. Unlike most other aliphatic ethers, dimethyl ether is not susceptible to autoxidation. This is of considerable importance for industrial applications. Numerous studies have confirmed that dimethyl ether is stable to atmospheric oxygen and does not form peroxides [3].

Dimethyl ether is converted to dimethyl sulfate [*77-78-1*] by sulfur trioxide (→ Dialkyl Sulfates and Alkylsulfuric Acids).

$SO_3 + CH_3$–O–$CH_3 \longrightarrow (CH_3)_2SO_4$

Addition of boron trifluoride to dimethyl ether results in the formation of $BF_3 \cdot CH_3OCH_3$ [*353-42-4*], *mp* −14 °C, *bp* 127 °C, a distillable liquid which fumes when exposed to moist air.

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a08_541

This addition compound is easier to handle than gaseous boron trifluoride.

In the presence of CoI_2, dimethyl ether reacts with carbon monoxide and water to form acetic acid [*64-19-7*] (→ Acetic Acid, Chap. 4.1.) [4].

$$CH_3\text{–}O\text{–}CH_3 + H_2O + 2\,CO \longrightarrow 2\,CH_3COOH$$

The reaction of dimethyl ether with hydrogen sulfide in the presence of a catalyst, e.g., tungsten sulfide (WS_2), gives dimethyl sulfide [*75-18-3*] [5].

$$CH_3\text{–}O\text{–}CH_3 + H_2S \longrightarrow CH_3\text{–}S\text{–}CH_3 + H_2O$$

The reaction of dimethyl ether to give unsaturated and saturated hydrocarbons proceeds in the presence of zeolitic catalysts [6].

$$CH_3\text{–}O\text{–}CH_3 \longrightarrow H_2C{=}CH_2 + H_2O$$

The catalytic conversion of dimethyl ether to formaldehyde has also been observed [7].

$$CH_3\text{–}O\text{–}CH_3 + O_2 \longrightarrow 2\,CH_2O + H_2O$$

3. Production

Until about 1975 dimethyl ether was obtained as a byproduct in the high-pressure production of methanol [8]. In this process up to 3 – 5 wt % dimethyl ether is formed. Dimethyl ether can be recovered in pure form by distillation of crude methanol. The development of the low-pressure methanol synthesis, particularly by Lurgi [9] and ICI [10], has resulted in the almost complete replacement of all high-pressure plants by 1980. The low-pressure processes, which require less severe conditions, produce only very small amounts of dimethyl ether (→ Methanol). As a result, special catalytic processes have been developed for the production of dimethyl ether.

The preparation of dimethyl ether from methanol in the presence of acidic catalysts on a laboratory scale has been known for many years [11]. Numerous methods have been discussed in the patent literature. For instance, aliphatic ethers can be prepared by heating alcohols in the presence of zinc chloride [12]. Other suitable catalysts are iron chloride, copper sulfate, copper chloride, manganese chloride, aluminum chloride, aluminum sulfate, chromium sulfate, alums, thorium compounds, aluminum oxide, titanium oxide, barium oxide, silica gel, and aluminum phosphate [13]. Aluminum oxide and aluminum silicate, with or without doping, are the most important catalysts for industrial use [14]. Figure 1 illustrates the process developed by Union Rheinische Braunkohlen Kraftstoff AG (now DEA Mineraloel AG, Wesseling) for the production of high-purity dimethyl ether (purity > 99.99). This quality is virtually odorless.

The catalytic dehydration of pure, gaseous methanol is carried out in a pipe reactor. The product is cooled in two stages and subsequently distilled to yield pure dimethyl ether. Small amounts of dimethyl ether are recovered from the off-gas in a scrubber and recycled to the reactor. Unreacted methanol is separated from water in a second column and also recycled.

Very pure dimethyl ether which is suitable as an aerosol propellant is obtained by special rectification processes.

Direct synthesis of dimethyl ether from synthesis gas ($CO + H_2$) has also been described [15].

Safety and Environmental Aspects. Dimethyl ether is a flammable gas. Water, foam, carbon dioxide, and dry chemical powders can be employed to control dimethyl ether fires. Fire extinguishers suitable for class C (Europe) or class B (United States) can be used. Endangered vessels must be cooled.

Although dimethyl ether is soluble in water and biologically easily degradable, large amounts of this compound should not enter the wastewater system because evaporation can cause the formation of explosive mixtures over the surface of the water.

Available data do not indicate a danger for the environment [2].

Quality Specifications and Analysis. Dimethyl ether is available in two commercial qualities:

- Technical grade contains up to 0.05 % methanol and contaminations with a strong odor.
- High-purity dimethyl ether, practically free of sulfur-containing and other substances with an unpleasant odor, can be used in

Figure 1. Dimethyl ether production by dehydration of methanol
a) Vaporizer; b) Reactor; c) Dimethyl ether column; d) Scrubber; e) Methanol column

the aerosol industry; the methanol content should not exceed 10 mg/kg for this quality.

The purity of dimethyl ether is determined by GC analysis. Oil and ash content are measured by special methods of evaporation and combustion.

Storage and Transportation. Dimethyl ether is usually stored as a liquid under pressure. It is transported in railway pressure tanks, tank trucks, and other pressure containers. Overseas transport is carried out in ISO tankers (International Shipping Organization).

Transportation is subject to the following regulations: GGVS/ADR GGVE/RID class 2, no. 2 F; ADN/ADNR class 2, no. 2 F; UN no. 1033; IMDG Code (Amendment 20-82), class 2.1, p. 2052.

Suppliers are DEA Mineraloel AG in Germany, Akzo Nobel Chemicals B.V. in the Netherlands, and DuPont & Nemours in Switzerland.

4. Uses

Up to the 1980s, the main industrial use for dimethyl ether was its conversion to dimethyl sulfate by treatment with sulfur trioxide. Dimethyl sulfate is used as a methylating agent. Of the 50 000 t of dimethyl ether produced in Western Europe in 1998, about 15 000 t was used in the production of dimethyl sulfate. The remaining 35 000 t of DME were used in the aerosol industry as a propellant. Owing to its high solubility coefficient, it also acts as a solvent in aerosol formulations. This property is of particular value in aerosol formulations which contain substances that are difficult to dissolve.

The reaction of dimethyl ether with carbon monoxide and water can be used in large-scale production of acetic acid instead of the methanol – carbon monoxide reaction. Future industrial uses of dimethyl ether could include the production of olefins, especially ethylene, propene, and butenes in the presence of zeolitic catalysts.

DME is also considered an alternative fuel for diesel engines (compression ignition) [16]:

- It has a low autoignition temperature
- It is an oxygenated fuel, and as a gas it helps establishing a good air – fuel mixture and consequently prevents soot formation
- It enables NO_x reduction.

5. Toxicology

Pure dimethyl ether is nontoxic. Inhalation experiments conducted on rats using concentrations of up to 20 000 ppm (2 vol % in air) over a period of 8 months did not lead to any deaths [3]. Contact with dimethyl ether is not irritating to the skin.

1. Physical Properties

The most important *physical and flammable properties* of dioxane are as follows:

bp	101.3 °C
fp	11.8 °C
d_{20}^{20}	1.0356
Latent heat of evaporation	413 kJ/kg
Heat of fusion	141 kJ/kg
Specific heat (20 °C)	1.76 kJ kg^{-1} K^{-1}
n^{20}	1.4224
Vapor pressure (20 °C)	4.13 kPa (41.3 mbar)
Dielectric constant (20 °C)	2.23
Surface tension (20 °C)	36.9 mN/m
t_{crit}	312 °C
p_{crit}	5.14 MPa
Flash point (closed cup)	11 °C
Flammable limits (in air)	
Lower limit	2 vol %
Upper limit	22 vol %
Heat of combustion	27 600 kJ/kg
Autoignition temperature	180 °C

1,4-Dioxane [*123-91-1*], $C_4H_8O_2$, M_r 88.11, is an extraordinary solvent, capable of solubilizing most organic compounds, water in all proportions, and many inorganic compounds.

Dioxane is a cyclic diether forming a six-membered ring with the following structure:

Synonyms for dioxane are *p*-dioxane, diethylene oxide, diethylene dioxide, diethylene ether, 1,4-dioxacyclohexane, dioxyethylene ether, and dioxan.

At ambient temperature, dioxane is a clear liquid with an ether-like odor. Its relative stability is similar to other aliphatic ethers, and it forms peroxides on exposure to air as they do. In spite of its exceptional solvent properties, its largest use is in stabilizing 1,1,1-trichloroethane and keep it from reacting with aluminum (see Chap. 8).

Reportedly, 1,4-dioxane was prepared by A. V. LOURENÇO in 1863 by reacting ethylene glycol and 1,2-dibromoethane [1]. However, commercial production did not occur until 1929.

Infinite *solubility* in dioxane can be expected from lower molecular mass aliphatic and aromatic liquid hydrocarbons, ethers, alcohols, ketones, and chlorinated hydrocarbons. Dioxane has solubility for animal and vegetable oils, paraffin oils, synthetic and natural resins, and some inorganic compounds and elements, such as iron chlorides, mercuric chloride, hydrochloric, sulfuric, and phosphoric acids, bromine, chlorine, and iodine.

Dioxane forms *azeotropic mixtures* with many compounds. Some common binary systems are given in Table 1.

2. Chemical Properties

As is characteristic of ethers, dioxane forms *peroxides* by air oxidation. These peroxides are often highly explosive and unstable. The peroxide of dioxane is 2-hydroperoxide 1,4-dioxane [*4722-59-2*] (**1**) [2], which decomposes to dioxanone [*3041-16-5*] (**2**) and water, and subsequently is hydrolyzed to form 2-(2-hydroxyethoxy)acetic acid [*13382-47-3*] (**3**):

The reaction rates favor formation of **3** and limit the peroxide concentration. However, di-

Water	100	82	87.8

* At 8 kPa.

oxane should be treated with the same precautions as other ethers to prevent peroxide formation. Inert gas padding (e.g., nitrogen atmosphere) may be used. Peroxide-containing ethers should not be evaporated or distilled to dryness. Peroxides can be destroyed by reducing agents, such as iron (II) or tin (II) chlorides or sodium bisulfite. Activated carbon, activated basic alumina, and the hydroxyl form of anion-exchange resins also remove peroxides [3].

Dioxane solubilizes and complexes with Cl_2, Br_2, I_2, and the halogen acids. These *complexes* can moderate halogenation or halogen acid reactions. For example, dioxane dibromide complex can brominate phenols, aromatic aldehydes or amines, and ketones. Conversely, chlorination can produce chlorinated dioxanes containing from one to eight chlorine atoms, with isomeric yields controlled by temperature, reaction conditions, and catalysts employed. Dioxanes containing fewer chlorine atoms can be used to prepare dioxane addition compounds, e.g., addition of ethoxy or ethyl groups using $NaOCH_2CH_3$ or CH_3CH_2MgBr, respectively.

2,3-Dichlorodioxane is particularly reactive. It condenses with aliphatic and aromatic acids, alcohols, and glycols to give diesters and ethers [4–6]. With ethylene glycol, the dicyclic isomers of 1,4,5,8-tetraoxadecahydronaphthalene are formed [7]. 2-Chloro-1,4-dioxene, made by dehydrohalogenation of 2,3-dichlorodioxane, can be polymerized or hydrolyzed to give dioxanone [8].

Although the *dioxane ring* is quite stable, it can be cleaved by strong acids at high temperature and pressure. Under such conditions, dioxane forms ethylene glycol diacetate and diethylene glycol diacetate when reacted with acetic acid anhydride [9]. In addition, benzoyl chloride and acetyl chloride catalyzed by $TiCl_4$ react with dioxane to form the 2-chloroethyl esters of benzoic and acetic acids [10], respectively.

Benzoyl peroxide catalyzes the reaction between α-olefins and dioxane to form *polymeric condensation products* [11]. The reaction requires a temperature of 80 – 140 °C and a reaction time of 5 – 10 h. The polymers are useful as lubricants. Similarly, tetrafluoroethylene reacted with dioxane at 110 °C with peroxide catalysis under pressure for 8 h forms analogous polymers of the following general structure [12]:

Numerous alternative catalysts are reported to be effective, including organic and inorganic peroxides, bases (e.g., borax, disodium phosphate, and hydrazine), zinc chloride, and phosphoric acid. Chlorofluoroethylenes containing at least two fluorine atoms and only one hydrogen atom yield similar products. The polymers formed can contain values of x from 1 to 25. A second polymer chain at another site on the dioxane ring can be formed by repeating the reaction with the first polymer product. The lower molecular mass products are volatile liquids of potential use as solvents. Higher molecular mass polymers are waxy solids and are regarded as possible lubricants.

Many *stable complexes* are reported in addition to those of the halogens mentioned previously. Some of the agents that give dioxane complexes are the following:

$AlBr_3$	LiBr	HCl
$AlCl_3$	LiCl	H_2SO_4
$AuCl_3$	LiI	H_3PO_4
BBr_3	$MnCl_2$	SO_2
BCl_3	$NiCl_2$	SO_3
BF_3	PF_5	$CuCl_2$	$PtCl_4$	
$CoCl_2$	$SbCl_5$	
$FeCl_3$	$ZnCl_2$	
$HgCl_2$	ZnF_2	

These complexes can be employed as catalysts, as moderating agents in carrying out reactions, such as bromination or sulfonation, or as anhydrous systems for acid reactions.

3. Production

1,4-Dioxane is manufactured commercially by *dehydration and ring closure of diethylene glycol.* Concentrated sulfuric acid (ca. 5 %) is used as a catalyst, although phosphoric acid, *p*-toluenesulfonic acid, and strongly acidic ion-exchange resins are recognized alternatives. Operating conditions vary; temperatures range from 130 to 200 °C and pressures range from a slight pressure to a partial vacuum (25–110 kPa). A favorable temperature is reported to be 160 °C. The process is continuous, with dioxane vaporized from the reaction vessel. The vapors are passed through an acid trap and two distillation columns to remove water and to purify the product. Yields of ca. 90 % are possible. 2-Methyl-1,3-dioxolane, acetaldehyde, crotonaldehyde, and polyglycol are unwanted byproducts.

Dioxane can also be prepared by dehydrohalogenation of 2-chloro-2′-hydroxydiethyl ether, by reacting ethylene glycol with 1,2-dibromoethane, and by dimerizing ethylene oxide either over $NaHSO_4$ [1], SiF_4, or BF_3 [13], or at elevated temperature with an acidic cation-exchange resin [14].

4. Environmental Protection

Dioxane, emitted into the atmosphere, is decomposed rapidly by hydroxyl radical oxidation, as are other hydrocarbons. The half-life is estimated to be 3.9 d [15]. The intermediates are probably short-lived hydrocarbon radicals; the ultimate products are carbon dioxide and water.

Dioxane is highly resistant to biotransformation, although it may possibly be oxidized by acclimated sewage microorganisms. Carbon adsorption purification of water containing dioxane has limited practicality because of the high (ca. 100-fold) ratio of carbon to adsorbed dioxane required for complete removal. Aeration of water containing dioxane is inefficient because of dioxane's extreme solubility and low vapor pressure. Dioxane can be decomposed by H_2O_2 by using $FeSO_4$ to catalyze the reaction at 25 °C. Oxidation of dioxane by chlorination is effective at 75 °C, but not at 25 °C [16].

5. Quality Specifications

The American Chemical Society (ACS) has published specifications for 1,4-dioxane [17]. A summary of the ACS requirements is as follows:

Color (APHA), max.	20
Peroxide (as H_2O_2), max.	0.005 %
fp, min.	11.0 °C
Nonvolatile residue, max.	0.005 %
Neutrality	to pass test
A maximum of 1.0 mL of 0.01 M H_3PO_4 to neutralize a 50-mL sample.	
Carbonyl (as HCHO), max.	0.01 %
Water, max.	0.05 %

Industrial grades are sold under producer specifications that are more or less demanding than for ACS grade. These specifications often include boiling and relative density ranges and a maximum acidity. Industrial specifications are accompanied by analytical methods or referenced methods.

Higher purity dioxane may be required for research or special industrial processes. Techniques have been described in the literature to remove traces of peroxides, acids, stabilizers, and aldehydes [3].

Samples should be handled to prevent air contact, and nonvolatile residue tests should not be performed on material that contains peroxides.

6. Storage and Transportation

The most important consideration in shipping and storing dioxane is to prevent peroxide formation. This is achieved by shipping and storing with a nitrogen pad. Failure to maintain an inert

atmosphere causes the material to exceed acid, peroxide, and possibly other specifications.

Mild steel drums and tanks are adequate for shipping and storage. To limit the fire hazard, all containers should be grounded to prevent static electrical charges from accumulating during transfer operations. All areas of storage must be equipped with explosion-proof equipment and be well ventilated. The material must be maintained above its freezing point in cases where temperatures may be $< 12\,^{\circ}C$ by use of insulation or heat.

The United Nations' recommendations include the shipping name "Dioxane," number UN 1165, and labeling using the warning as a flammable liquid hazard class 3. The International Maritime identifies dioxane in class 3.2.

7. Legal Aspects

The U.S. National Toxicology Program (NTP) and the International Agency for Research on Cancer (IARC) have listed dioxane as a possible carcinogen on the basis of extreme high-dose lifetime animal studies discussed in Chapter 10. These listings may require special labeling or restrictions; national and local regulations should be consulted [18].

8. Uses

The largest single use of 1,4-dioxane is the *stabilization of 1,1,1-trichloroethane* against chemical attack by aluminum [19], [20]. The aluminum oxide film prevents the metal from reacting with 1,1,1-trichloroethane until the film is disturbed. When the bare metal contacts 1,1,1-trichloroethane, chlorine is extracted from the solvent to form $AlCl_3$, which causes dehydrohalogenation of 1,1,1-trichloroethane to produce HCl and vinylidene chloride ($CH_2 = CCl_2$). Dioxane is the foremost inhibitor of these reactions. An insoluble dioxane–aluminum chloride complex is formed, which deactivates the catalyst and seals any openings in the Al_2O_3 film.

Dioxane is used as a *solvent* in the formulation of inks, coatings, and adhesives, and as solvent for extracting animal and vegetable oils. As a *chemical intermediate,* dioxane reaction products are useful as insecticides, herbicides, plasticizers, and monomers. The oxonium complexes of dioxane with salts, mineral acids, halogens, and sulfur trioxide are used as *catalysts* and as *reagents* for anhydrous acid reactions, brominations, and sulfonations. In the laboratory, dioxane is useful as a *cryoscopic solvent* for molecular mass determinations and as a *stable reaction medium* for diverse reactions. Historically, dioxane is reported to be valuable in *polymer manufacture* and as a *solvent* for natural and synthetic resins, including cellulose derivatives, polyvinyl acetal resins, acrylonitrile – methyl vinyl pyridine copolymers, and others.

9. Economic Aspects

Recognized *manufacturers* of dioxane are

BASF Aktiengesellschaft, Ludwigshafen, Federal Republic of Germany
CPS Chemical Co., Old Bridge, New Jersey, United States
Dow Chemical Co., Terneuzen, The Netherlands
Grant Chemical Co., Baton Rouge, Louisiana, United States
Osaka Organic Chemical Industries Co., Japan
Sanraku-Ocean Co., Japan
Toho Chemical Industry Co., Japan
Ugine-Kuhlmann, Frankfurt, Federal Republic of Germany
Union Carbide, South Charleston, West Virginia, United States

Capacity of known producers was estimated to be 11 000 – 14 000 t in 1985.

10. Toxicology and OccupationalHealth

The *acute toxicity* of dioxane is relatively low. The oral LD_{50} (rats) is 5170 mg/kg; by skin absorption, the LD_{50} (rabbits) is 7600 mg/kg. The LC_{50} (rats) with a 4-h exposure is 14 260 ppm (51 880 mg/m^3) [21]. *Acceptable occupational standards* are as follows:

American Conference of Governmental Industrial Hygienists (ACGIH), TLV–TWA	25 ppm (90 mg/m^3) [22] "skin" notation
U.S. Occupational Safety and Health Administration (OSHA)	100 ppm (360 mg/m^3)
Deutsche Forschungsgemeinschaft (MAK)	>50 ppm (180 mg/m^3) [23] IIIB notation: suspected of carcinogenic potential
Sweden (1975)	25 ppm (90 mg/m^3)
USSR (1980)	3 ppm (10 mg/m^3)

Processes that employ dioxane should be designed to protect workers against skin and eye exposure, as well as excessive vapor inhalation. The odor warning properties of dioxane are not adequate to afford protection. Exposure to high concentrations may cause respiratory irritation and damage to the kidney and liver.

Early, chronic *animal testing* (rodents) at extremely high doses (7 – 18 000 mg/kg in water) resulted in nasal and liver tumors and in liver and kidney damage. A follow-up study with exposures at 10 000, 1000, and 100 mg/kg in water confirmed the earlier results at high dose, but the lower dose testing showed definite indications of a threshold [24]. Animals exposed to 1000 mg/kg in water suffered varying degrees of kidney and liver injury but no treatment-related tumors. The animals dosed with 100 mg/kg (in water) experienced no adverse health effects.

A number of tests have been employed to determine whether or not dioxane caused these nasal and liver *tumors* by direct interaction with deoxyribonucleic acid (DNA) or by some other mechanism. Included were mutagenicity tests on microorganisms to observe if genetic changes occurred, e.g., the Ames bacterial mutagenicity test and a test to detect DNA repair in liver cells [25], [26]. Further tests using relatively high doses of ^{14}C-radiolabeled dioxane were conducted; the liver DNA was isolated and measured for trace quantities of radioactivity from DNA–dioxane reaction products [26]. Strong positive responses in these tests would have provided evidence of possible carcinogenicity. However, no mutagenicity or DNA reaction products were discovered [25], [26]. Therefore, dioxane may cause tumors in rodents via an alternate mechanism, possibly by recurrent tissue damage [26].

Pharmacokinetic and metabolic studies using ^{14}C-radioactive dioxane demonstrated that low doses of dioxane are eliminated in the urine as 2-hydroxyethoxyacetic acid (HEAA) [27–30]. Conversion of dioxane to HEAA is nearly complete, as indicated by the observed 118 : 1 ratio of HEAA to dioxane; the reaction is rapid, with a dioxane half-life of ca. 1 h. However, the process has a saturation point, and when this is exceeded by a high dose, elimination requires much more time.

The threshold effect is further supported by a 2-year inhalation study conducted on rats at a concentration of 111 ppm [31]. Unlike the high dose drinking water studies, no adverse health effects were observed, including no increase in tumor incidence.

Human exposures, estimated to have been at 470 ppm, have resulted in deaths. Three epidemiologic studies have been made of plant workers exposed to concentrations of up to 51 ppm. Each of these studies found no evidence of any adverse health effects.

These data were reviewed by the ACGIH with the following conclusion: "... In view of the findings of tumors in both liver and lung at or near the 10 000 ppm dietary level, and the lack of such findings at inhalation exposure levels slightly above 100 ppm for two years, dioxane has been classed by the TLV Committee as an animal tumorigen of such low potential as to be of no practical significance as an occupational carcinogen at or around the former TLV of 50 ppm." The carcinogenicity of dioxane at high-dose exposures appears to be the result of repeated tissue injury. Therefore, controlling exposures to levels below those that would cause organ injury should prevent any significant risk of cancer.

1. Introduction

Systematic pioneering studies in the 19th century, especially those of LOUIS PASTEUR (1822 – 1895) and ROBERT KOCH (1843 – 1910), showed that diseases are caused by microorganisms. Simultaneously, microorganisms were found to cause spoilage of food, cosmetics, drugs, and other materials. Preventing microorganisms from causing disease or destroying products led to the concept of disinfection.

Even prior to Koch's studies, IGNAZ PHILIP SEMMELWEIS, working in Vienna, Austria in 1847, dramatically reduced maternal mortality in his hospital when he ordered physicians to wash their hands with chlorinated lime prior to assisting in birth. Although misunderstood by many of his colleagues, SEMMELWEIS was successful in introducing hand disinfection without realizing the importance of bacteria [1], [2].

JOSEPH L. LISTER, who was influenced by Pasteur's studies, was equally successful in England in 1867, when he introduced the use of phenol solutions for treating skin wounds, thereby preventing severe infection [3].

Thereafter, successes followed rapidly. In 1888, PAUL F. FÜRBRINGER introduced the use of alcohol for disinfecting hands. The first proprietary disinfectant was Lysol (Schülke & Mayr), which appeared on the market in 1892 and proved its efficacy during the 1893 cholera epidemic in Hamburg, Germany. The disinfective properties of formaldehyde were recognized ca. 1900. This was followed in 1912 by the introduction of less toxic phenolic compounds, which superseded the use of cresols and tar oils for more delicate disinfection procedures.

Consequently, disinfectants and antiseptics rank high and they are becoming more and more important as protection against infections in the medical field and for production hygiene, particularly in food processing.

The discovery and development of antibiotics in the second half of this century seemed to have banned the threat posed by infectious diseases so that the significance of disinfectants rapidly declined for physicans and in public opinion. This development went the wrong way and has changed meanwhile.

1) All over the world nosocomical infections (i.e., in hospital acquired infectious diseases) play an increasingly important role not only regarding mortality and morbidity of patients but also in view of economy. The German Hospital Society reported 638 000 – 706 000 cases of nonsocomial infections in 1987 for Germany on average. These patients had to stay in hospitals 10 days longer than normal [4]. In the United States additional costs of US $ 2100 per nosocomical infection have been calculated [5]. In Germany it is estimated that nowadays of all patients being hospitalized for different reasons 1×10^6 suffer from nosocomical infections in addition to their original disease. The most important prophylactic measure is the compliance with hygienic and disinfection plans.

10.1002/14356007.a08_551

2) Many well known pathogens which were supposed to have been overcome have developed a resistance against antibiotics. Infectious diseases caused by multiresistant microorganisms are difficult to treat. Their transmission can be restricted or inhibited by specific disinfection measures [6].
3) New infective agents are appearing or identified for the first time, e.g., *Helicobacter pyloris* causing gastritis or gastric carcinoma, Hepatitis-C-virus against which vaccination is still not possible, or *Escherichia coli* type EHEC (*E. coli* 0157:H7), causing the hemolytic uremic syndrom through food poisoning [7]. A careful hygiene and disinfection help to significantly reduce the danger emanating from such pathogens.

2. Definitions

The goal of *disinfection procedures* is to prevent transmission or spread of organisms that cause disease or spoilage. The following definition is frequently quoted in international publications: "Disinfection is the specific elimination of undesirable microorganisms for the purpose of preventing their transmission by interfering with their structure or metabolism irrespective of their functional state" [8]. This rather broad statement has been replaced by more manageable definitions, all of which are basically similar but which address only the medical aspect of this term. Disinfection has been defined as:

1) killing or inactivating all disease-causing organisms by chemical agents or physical procedures (Roche Lexikon, 1984) [9]
2) removing or destroying pathogenic microorganisms (Oxford Companions to Medicine, 1986) [10]
3) killing or irreversibly inactivating all causative agents of transmissible diseases [11].

In some circumstances, notably in the United States, the term "disinfectant" is customarily used only for active agents applied to inanimate objects. According to the EPA definition: "Disinfectants destroy or irreversibly inactivate infectious or other undesirable bacteria, pathogenic fungi, or viruses on surfaces or inanimate objects." Agents for application to living tissue are referred to as "antiseptics." In this article, "disinfectant" refers to active agents for both living tissue and inanimate objects.

Common to all definitions is the fact that disinfection is directed only against organisms that are considered harmful. The irreversible inactivation of the causative agent is considered to be essential by most definitions, except the British one, which also permits removal. Reber [8] is the only one to extend the definition of disinfection to include product protection.

Distinction should be made among disinfection, sterilization, and preservation. *Sterilization* refers to the complete destruction or irreversible inactivation of all microorganisms. *Preservation* is aimed at inhibiting multiplication of microorganisms in materials that are likely to spoil, with activity extending over a relatively long period.

Applying disinfectants means a careful selection of the range of microorgansims that will be inactivated by the corresponding preparation. The contained active agents as well as use concentrations and contact times are decisive.

In general it can be stated that disinfectants are formulated to inactivate bacteria and fungi. Efficacy against viruses, in particular against uncovered viruses, can be limited. Not all preparations inactivate bacterial spores, high concentrations of active agents are absolutely necessary.

3. Application

The aim of a disinfection measure will only be achieved if an appropriate disinfectant for the intended purpose is chosen observing the recommended use concentration and time and provided all parts of the body or the object to be treated come into contact with the preparation or its solution.

Typical application fields for disinfectants are in hospitals and other medical institutions in veterinary medicine; in many industrial areas for maintenance of a good production hygiene (e.g., in the pharmaceutical, food processing and cosmetics industry, in catering establishments, etc.); and in public facilities (swimming pools, prisons, barracks etc.).

Disinfection is important in agriculture for disinfection of barns used for intensive animal

husbandry and disinfection of working surfaces and equipment used in greenhouses (to maintain a monoculture free of outside germs).

In public services, sanitation of drinking water and swimming pools must be considered.

In private households disinfection measures may be advisable for the care of seriously ill patients or for food processing.

Within the mentioned application fields specific disinfection procedures with different types of preparations are necessary for different purposes. What is meant by "different purposes" may be demonstrated in the field of medical applications.

1) Skin and mucous membrane disinfection of patients, e.g., before surgical treatment, injections, punctures, catheterization of the bladder, or for antiseptic wound treatment. With these measures a transmission of microorganisms in primary sterile areas will be avoided.
2) Hygienic hand disinfection to inactive microorganisms on the hands of medical staff to avoid the transmission of microorganisms from one patient to the other via the hands or from contaminated surfaces and equipment to patients via the hands.
3) Surgical hand disinfection is executed before surgical treatment by the operating team before gloves are put on. The endogenic mixed flora, too, must be inactivated in order to prevent microorganisms from entering the opened body during operation in case the gloves are defect.
4) Instrument disinfection by immersion of used instruments into disinfection solutions with the aim to protect the staff against infections before further handling (e.g., cleaning, sterilization, etc.). Patients are also protected if thermolabile material is handled (e.g., endoscopes).
5) Thermochemical instrument disinfection in (washing) machines at 50 – 60 °C instead of immersion into disinfection solutions.
6) Surface disinfection by rubbing and wiping the surfaces of treatment tables in consulting rooms, the surfaces of equipment for treatment and diagnosis, etc., or floors.
7) Laundry disinfection, disinfection of excrements and other special applications.

4. Efficacy Testing Methods, Requirements for Efficacy

Up to now many countries have their own test methods to evaluate a disinfectant. These methods may be found compiled in national guidelines for normalization or in guidelines published by scientific associations. An example are the test methods of the DGHM (German Society for Hygiene and Microbiology) [12]

Suspension tests and germ carrier tests are most important for testing disinfectants.

In *suspension tests* a suspension of the microorganisms is mixed with the disinfectant in a given test concentration. After the desired exposure time the effect of the disinfection is interrupted by suitable methods (dilution or chemical neutralization), surviving germs are counted and deducted from the amount of germs that remained without any influence of the disinfectant. From both figures the logarithmic germ count reduction is calculated. The suspension test also allows to determine the influence of disturbing substances such as blood, or albumin on the efficacy.

Germ carrier tests allow to simulate practice-relevance conditions. Microorganisms are brought onto germ carriers made of glass, metal, plastic, textiles, etc. After drying, the carriers are placed into the disinfection solution or they are wetted with the solution. The further procedure is similar to the suspension test.

For hand, skin or mucous membrane disinfectants tests on the corresponding epithelia are carried out. These tests have to be organized like chemical trials.

Since 1990 a European group of experts associated to CEN (European Committee for Standardization) in Brussels has been establishing European standards for testing disinfectants and antiseptics and an obligatory profile for tests and requirements. After tests in phase 1 where it is evaluated whether a formulation has disinfecting properties at all, the suitability for a particular application field is investigated in phase 2.

Corresponding standards have already been released for the application field hand disinfection in the medical area. Standing for all other test methods, they are introduced as follows: In a suspension test EN 12054 the bactericidal effect

is investigated against a range of four bacterial strains in short exposure times. These bacteria represent all other bacteria. If the test requirements are met, the efficacy on hands is investigated in a test under practical conditions. In case the formulation is intended for hygienic hand disinfection, the hands of volunteers are heavily contaminated with *E. coli* and afterwards treated with the disinfectant or with 2-propanol (60 vol %) in a reference procedure (EN 1500). The obtained germ count reductions are compared. The test preparation must be at least as effective as 2-propanol in the reference procedure.

The efficacy of a formulation for surgical hand disinfection is tested on the normal hand, i.e., without special contamination and is compared with a reference procedure using 1-propanol (60 vol %) EN 12791.

For the application field hygienic hand disinfection two different methods have been accepted throughout Europe. In Germany, Austria, and in parts of Switzerland alcohol preparations are rubbed into the hands, in other countries aqueous washing preparations with a bactericidal effect are used. The aforementioned EN 1500 refers to such rubb-in preparations. EN 1499 is effective for washing preparations. In the reference procedure (EN 1499) potassium soap is used. The test preparation must have a better effect than the soap in a test under practice-relevance conditions on the hand. If necessary, efficacy tests against mycobacteria, fungi, or viruses must also be added. Corresponding standards are being worked out.

For all other application fields for disinfectants and antiseptics test methods and requirement profiles have also been issued as ENs or are being developed.

All valid standards can be obtained at DIN (in German language), BSI (in English language) or at AFNOR (in French language).

5. Formulations

Disinfectant formulations mostly contain a combination of active ingredients to satisfy user demands, and to fulfill the appropriate test procedures. In addition, additives must be incorporated to achieve good skin tolerance, materials compatibility, cleaning power, and other goals (see Table 1).

The specific spectrum of effectiveness of the active ingredients is discussed in Chapter 6. However, because closely related chemical substances commonly exhibit marked differences in potency, referring globally to aldehydes, phenols, etc. as disinfectants is inappropriate.

Currently, the preferred active ingredients are from the following classes of chemicals: aliphatic and aromatic alcohols, aldehydes, peroxy acids, phenols, cation-active compounds, amphoteric surfactants, alkylamines and inorganic oxidizing agents.

The benefits and risks associated with commercial products can only be assessed on the basis of test results for the complete preparation. Definitive conclusions are impossible if they are based solely on the properties of individual ingredients.

Examples of some preparations used for different applications are given in Table 2. Some preparations are used without further dilution, whereas others must be diluted prior to use. Many products contain active ingredients from several different chemical classes.

6. Active Ingredients

6.1. Alcohols

Ethanol [*64-17-5*] and the two propanols (1-propanol [*71-23-8*] and 2-propanol [*67-63-0*]) are essentially the only aliphatic alcohols used, even though they are effective only at high concentration. Their advantage lies in their water miscibility, rapid evaporation, and favorable pharmacologic and toxicologic properties [13]. Higher alcohols are more effective as antimicrobial agents, but their low volatility, unpleasant odor, and danger of resorption exclude their use.

The concentration of primary alcohol effective within 2 min against gram-negative and gram-positive bacteria, when tested in a suspension test, is as follows [14]:

Chain length	C_1	C_2	C_3	C_4	C_6	C_{12}
Concentration, %	60	50	20	10	5	15

Maximum effectiveness is reached with alcohols having six to eight carbon atoms. 2-Ethylhexanol [*104-76-7*] appears to be the most

Table 1. Common disinfectant additives

Additive	Disinfectant use [a]			
	Hand	Skin	Instrument	Surface

∗ PVP = Polyvinylpyrollidone

effective. When combined with solvents and emulsifiers, a 0.2 % solution of 2-ethylhexanol kills gram-negative organisms within 15 min [15]. Despite its odor, these favorable properties have led to limited use of 2-ethylhexanol in combination with other agents in concentrated surface disinfectants that are diluted with water before use.

The most important application of short-chain alcohols is for disinfecting skin and hands. The alcohols are mostly combined with substances having germistatic activity. These alcohols are not suitable for disinfection of mucous membranes. Another application is for surfaces that must be disinfected rapidly, e.g., examination tables and working surfaces.

The maximum potency of ethanol is as a 70 % aqueous solution. For example, in a germ carrier test using gauze as the substrate, *Staphylococcus aureus* is killed by a 50 or 80 % solution within 10 min, but is killed within 5 min by a 60 – 75 % solution [16]. The alcohols are ineffective against spores of bacteria. Ethanol in concentrations below 75 – 80 %, 2-propanol, and 1-propanol are ineffective against unenveloped viruses like the polyvirus as a representative for

enteroviruses. However, lipophilic viruses like the herpesvirus are rapidly and effectively inactivated by all three alcohols [17], [19]. The effectiveness of an ethanol-based hand disinfectant against polio virus within 10 – 60 s has been proven in a clinical trial. 2-propanol (60 vol %) in comparison was absolutely ineffective even after 60 s [18].

Among aromatic alcohols, benzyl alcohol [*100-51-6*], $C_6H_5CH_2OH$, phenethyl alcohol [*60-12-8*], $C_6H_5CH_2CH_2OH$, and phenoxyethanol [*122-99-6*], $C_6H_5OCH_2CH_2OH$, and the mixture of isometric phenoxypropanols (1-phenoxypropanol-2 [*770-35-4*] and 2-phenoxypropanol-1 [*4169-04-4*] find limited application, generally in combination with other active agents. These compounds have germicidal as well as germistatic activity (Table 3). They are more toxic than short-chain aliphatic alcohols [20]. An overview of the properties of alcohols as disinfectants has been published [21].

6.2. Aldehydes

Certain aldehydes have proved to be excellent agents for disinfecting instruments and surfaces. However, aldehydes are not used as skin disinfectants mainly because their local tolerance is unacceptable. Within the large group of aldehydes only very few have microbiocidal properties. For example, succinaldehyde and glutaraldehyde are extremely effective whereas adipaldehyde and malonaldehyde are ineffective. On the other hand the few active aldehydes are effective against a broad spectrum of infective agents provided the contact times and concentrations are chosen correctly.

The most commonly used aldehydes are formaldehyde [*50-00-0*], HCHO; succinaldehyde [*638-37-9*], $HCOCH_2CH_2CHO$; glutaraldehyde [*111-30-8*], $HCO(CH_2)_3CHO$; 2-ethylhexanal [*123-05-7*],

$CH_3(CH_2)_3CH(CH_2CH_3)CHO$; and glyoxal [*107-22-2*], HCOCHO. As with alcohols, the most effective monoaldehydes have seven or eight carbon atoms, but their pungent odor limits their use. In this connection formaldehyde must be regarded differently. This might be due to its pronounced tendency to form oligomeres on the one hand and hydrates on the other hand. Thus, marked differences in efficacy are noticeable when the results of surface and suspension tests are compared [15]. In the suspension test, a 1 % solution of formaldehyde is effective in less than 30 min against a wide range of fungi and bacteria and, thus, is considerably less effective than, e.g., 2-ethylhexanal, a 0.1 % solution of which kills all microorganisms within 2.5 min. On the other hand, a 0.3 % solution of formaldehyde kills *Staphylococcus aureus* on surfaces within 4 h, whereas an equally strong solution of 2-ethylhexanal is inadequate even after contact for 6 h.

These results clearly demonstrate the advisability of combining active ingredients to formulate effective and acceptable preparations. This is especially important because the effects of combination preparations are frequently not only additive, but also synergistic. For example, a product (Buraton 10 F), which at its working strength contains 0.045 % formaldehyde, 0.01 % glutaraldehyde, 0.0025 % 2-ethylhexanal, and 0.07 % glyoxal, meets the DGHM specification for a surface disinfectant because it is effective within 1 h both in the suspension test and the surface test. Often aldehydes are combined with cationic compounds in commercial preparations. So the concentration of aldehydes can be lowered and the acceptability is increased (reduction of smell).

Among the dialdehydes, glyoxal was ineffective against the usual spectrum of microorganisms in the suspension test (30 min exposure, 1 % solution). On the other hand, a 0.2 % solution of succinaldehyde or glutaraldehyde was effective within 15 and 2.5 min, respectively (if the effect on *Candida albicans*, which required a longer contact time, is excluded). The same concentration was also effective within 1 h against *Staphylococcus aureus* on surfaces; for glyoxal this effect required only a 0.1 % solution. Therefore, glyoxal is useful as a surface disinfectant only when combined with other active ingredients.

Aldehydes are effective virucidal agents against lipophilic viruses and enteroviruses, such as the Coxsackie viruses or polioviruses. They are to some extend less effective against papovaviruses such as the SV 40 virus [22], [23].

Succinaldehyde and glutaraldehyde have a low tendency to be adsorbed onto plastic materials. This property, combined with their gen-

Table 3. Effective concentration and contact time to kill germs with aromatic alcohols [15]

Aromatic alcohol	Concentration, %	Contact time, min			
		Escherichia coli	*Pseudomonas aeruginosa*	*Proteus mirabilis*	*Staphylococcus aureus*
Benzyl alcohol	1	>30	>30	>30	>30
Phenethyl alcohol	1.25	2.5	2.5	2.5	>30
	2.5	2.5	2.5	2.5	5
Phenoxyethanol	1.25	15	2.5	2.5	>30
	2.5	2.5	2.5	2.5	>30

erally broad activity and excellent materials compatibility, has led to their use as agents capable of disinfecting (contact period 15 min) or almost sterilizing (contact period 10 h) delicate thermolabile instruments, e.g., endoscopes. The best known products are Gigasept/Gigasept FF (succinaldehyde – dimethoxytetrahydrofuran) and Alhydex – Cidex (glutaraldehyde). In U. S. journals such preparations are defined as "sterilizer". The treatment of an instrument with the preparation (immersion, rinsing, drying) does not guarantee sterility of the instrument. Therefore, this term is not used in Europe, and the term "disinfection" is preferred. A survey on the properties of glutaraldehyde is given in [24].

6.3. Peroxy and Peroxo Acids

Peroxycarboxylic acids and inorganic peroxo acids contain active oxygen and are extremely effective disinfectants. Because these compounds also act as strong oxidants, formulating stable, liquid preparations that contain these active ingredients combined with additives that have cleaning, skin protective, anticorrosive, or other properties is difficult.

Peroxycarboxylic acids may be prepared in solution from reactive carboxylic acid derivatives (e.g., acid chlorides, acid anhydrides, and possibly esters or amides) and excess H_2O_2. The direct reaction of carboxylic acids with H_2O_2 requires the presence of a strong mineral acid such as sulfuric acid. Reviews on peroxycarboxylic acids as disinfectants have been published [25], [26].

Solid reactive acid derivatives can be mixed with solid hydrogen peroxide sources (e.g., peroxycarbonates, peroxyborates, or similar substances). In this case, the peroxycarboxylic acid is not formed until water is added. Other additives may be included in such a formulation, because the final solution must remain stable for only a few hours. Such solutions also exhibit a broad spectrum of antimicrobial activity [27], [28].

Aliphatic Peroxycarboxylic Acids.

Peracetic acid [*79-21-0*], CH_3CO_3H, was described as a germicidal substance as early as 1902 [29].

In spite of its effectiveness at low concentration against all types of microorganisms (Table 4), peracetic acid has not found wider acceptance because of its corrosive properties, penetrating odor, the danger of explosive reactions, and its limited stability. There are also some discussions about possible toxicity of peracetic acid [30], [31]. Peracetic acid is used for disinfection of artificial kidneys, linen, for treating ion exchange resins or for use in food industry.

Monoperoxyglutaric acid [*3851-97-6*], $HO_2C(CH_2)_3CO_3H$, exhibits a broad spectrum of antimicrobial activity. The compound is odorless, essentially nonvolatile, and quite stable in solution [35].

Monoperoxysuccinic acid [*3504-13-0*], $HO_2CCH_2CH_2CO_3H$, is generated only during the preparation of the aqueous application solution as described previously. The compound is relatively unstable. It inactivates viruses not only by capsid alteration, but also by RNA fragmentation [36].

Peroxyformic acid and peroxypropionic acid resemble peracetic acid in their effectiveness, but both are difficult to apply and are used only occasionally.

Aromatic Peroxycarboxylic Acids. These compounds are frequently much more stable than the aliphatic acids. However, their low water solubility and limited stability in alcohols have prevented their practical application. The antimicrobial properties of some members of this class, e.g., peroxybenzoic acid, peroxyanisic

Table 4. Contact time to kill germs with four dilutions of peracetic acid [33], [34]

Microorganism	Contact time, min			
	0.5 %	0.05 %	0.005 %	0.0005 %
Bacillus subtilis (spores)	1	>30	>30	>30

Staphylococcus aureus	1	1	5	10
Trichophyton mentagrophytes	5	>30	>30	>30

acid, and chloroxyperbenzoic acid, have been described [37].

Monoperoxyphthalic acid is commercially available as the hydrated magnesium salt [38]. The compound is used in a surface disinfectant which is a white granulate.

Inorganic Peroxo Acids. Peroxomonosulfuric acid [*7722-86-3*], HO_3SOOH, and its alkali-metal salts have been found to be as effective as organic peroxy acids . These compounds also have good overall effectiveness against viruses [39]. Viruses including papovaviruses which are resistant to other disinfectants are deactivated. The absence of toxic vapors that might endanger personnel or patients is noteworthy. However, peroxomonosulfuric acid can oxidize chloride to chlorine. So, if the solutions are prepared with tap water which contains relatively high amounts of chloride, the chlorine smell may influence the user in favor of the compound.

6.4. Phenols

Phenol [*108-95-2*], C_6H_5OH, the simplest member of this class, was introduced as an antiseptic in 1867 by Joseph L. Lister. Systematic studies were undertaken around the turn of the century to determine the effect of substitution on disinfectant properties [40], [41]. Alkyl substituents were found to increase efficacy, with those having 5 – 7 carbon atoms being the most effective. Substitution by chlorine or bromine exerted an even greater effect. These relationships have been discussed in detail [42].

In general, phenols are effective germicidal and germistatic agents against bacteria, fungi, and lipophilic viruses, but are not effective against spores and hydrophilic viruses. They are markedly more effective in a weakly acidic rather than in an alkaline environment. However, their water solubility under acidic conditions is low. Surfactants may impair the efficacy of phenols.

Phenols are frequently incorporated into commercial soap concentrates; the diluted solution is used to disinfect surfaces and instruments, and occasionally skin and hands. Phenol derivatives are also incorporated as the active germistatic agents in alcohol-based products.

Increased discussions on pharmacological, toxicological, and ecological properties of phenols have reduced use to relatively few, preferably nonhalogenated compounds. This is especially true for Middle European and Scandinavian countries, but not for English speaking countries. Polychlorinated phenols, such as pentachlorophenol and even hexachlorophene, are no longer used.

The efficacy and pharmacologic and chemical properties of the phenols have been described in detail [43].

Nonhalogenated Phenols. *2-Phenylphenol* [*90-43-7*], $C_6H_5C_6H_4OH$, M_r 170.21, (2-hydroxybiphenyl, 2-hydroxydiphenyl, *ortho*-phenylphenol) *mp* 55.5 – 57.5 °C, *bp* 280 – 284 °C, vapor pressure 70 Pa at 100 °C, solubility in water 0.07 g in 100 g, forms colorless to pale yellow crystalline flakes.

This substance is more effective against gram-negative bacteria and fungi than against gram-positive cocci (Table 5) [44]. No effect was observed on enteroviruses when exposed for 10 min at concentrations up to 12 % [45]. However, adenoviruses and vacciniaviruses were rapidly inactivated by 0.12 % solutions. A combination of 2 % 2-phenylphenol, 18 % 1-

Table 5. Germicidal concentration after 30 min contact with 2-phenylphenol

Microorganism *	Germicidal concentration, %		
	pH 4.5	pH 7	pH 8.5
Gram-negative bacteria	0.005 – 0.01		0.0125 – 0.025
Staphylococcus aureus	0.1		0.25
Candida albicans	0.01 – 0.0125	0.025	

* Initial concentration 10^9/mL.

propanol – 2-propanol, and soap was effective against hepatitis B viruses [46].

Based on its well-researched and generally favorable toxicologic properties, 2-phenylphenol is currently the most widely used phenol. It is approved in many countries for treating citrus fruit. The WHO has set the acceptable daily intake to 0.2 mg/kg and limited maximum daily intake to 1 mg/kg.

Thymol [*89-83-8*], 2-[$(CH_3)_2CH$]C_6H_3-5-(CH_3) OH, M_r 150.22, 2-isopropyl-5-methylphenol, *mp* 51.5 °C, *bp* 232 °C, vapor pressure 12.7 Pa at 40 °C, solubility in water 0.098 g in 100 g at 25 °C, forms colorless crystals.

Thymol is a component of many natural essential oils and, probably for this reason, has been incorporated as a component of antimicrobial mouth and throat antiseptics. Solutions containing 0.03 – 0.05 % are effective against fungi [47].

Eugenol [*97-53-0*], 4-$(H_2C{=}CHCH_2)$ C_6H_3-2-(OCH_3) OH, M_r 164.20, 2-methoxy-4-(2-propenyl)phenol, *mp* – 9 °C, *bp* 225 °C, is a clear liquid.

Eugenol, also a natural substance, is quite effective against bacteria and fungi. Its tendency to form complexes with metal ions, its sensitivity to oxidation, and its intensive smell of cloves limit general use of this compound.

4-tert-Amylphenol [*80-46-6*],

$C_2H_5C(CH_3)_2C_6H_4OH$, M_r164.25, 4-*tert*-phenylphenol, 4-(2-methylbutyl)phenol *mp* 88 – 89 °C, *bp* 225 °C, is extremely effective against gram-positive bacteria and for this reason is still used in the United States in surface disinfectants.

Although they are quite effective, cresols and xylenols are no longer extensively used because of their toxic properties and strong odor. They were once used extensively in cresol – soap solutions as described in various pharmacopoeias.

Halogenated Phenols.

4-Chloro-3-methylphenol [*59-50-7*], $ClC_6H_3(CH_3)OH$, M_r 142.59, 4-chloro-*m*-cresol, *mp* 55.5 °C, *bp* 235 °C, vapor pressure 700 Pa at 100 °C, solubility in water 0.4 g in 100 g, is a colorless powder.

4-Chloro-3-methylphenol is currently an important chlorophenol; it is used as a commercial preservative as well as an active agent in disinfectants. In suspension tests, chlorocresol was found to be effective within 30 min against dermatophytes at concentrations of 0.005 – 0.01 % (pH 4.5) and at 0.0125 – 0.025 % against *Candida albicans*.

2-Benzyl-4-chlorophenol [*120-32-1*], $C_6H_5CH_2C_6H_3(Cl)OH$, M_r 218.69, Clorophene, *mp* 48.5 °C, *bp* 160 – 162 °C at 466 Pa, vapor pressure 13 Pa at 100 °C, solubility in water 0.007 g in 100 g, occurs as colorless crystals.

Chlorophenol is extremely effective. In the suspension test, a concentration of 0.025 % is adequate to kill all types of microorganisms within 30 min [44].

4-Chloro-3,5-dimethylphenol [*88-04-0*], $(CH_3)_2ClC_6H_2OH$, M_r 156.61, chloroxylenol, *mp* 115.5 °C, *bp* 246 °C, solubility in water 0.05 g in 100 g, occurs as colorless prisms or needles.

Chloroxylenol is used in combination with other phenols. It is more effective against gram-positive bacteria than against gram-negative bacteria [48].

Other halogenated phenols used as disinfectants include chlorothymol, 2-chloro-6-methyl-4-benzylphenol, 4-bromo-2,6-dimethylphenol, 2,3,4,5-tetrabromo-6-methylphenol, and 2,4,4′-trichloro-2′-hydroxydiphenyl ether (Triclosan).

Triclosan is used as active agent in germicidal soap.

6.5. Cation-Active Compounds

Cation-active compounds were introduced as antimicrobial agents in 1935 by GERHARD D. DOMAGK. This class of disinfectants includes compounds of widely differing structures, such as quaternary ammonium compounds and guanidinium and pyridinium derivatives. The first generation of cation-active compounds showed effectiveness against gram-positive bacteria at low concentration, low activity against gram-negative bacteria, and ineffectiveness against mycobacteria. Continuous development and testing of new structures for activity have produced the relatively well-balanced compounds currently available. However, even such substances are inactive against mycobacteria.

Benzalkonium chloride [*68391-01-5*], $[C_6H_5CH_2N(CH_3)_2C_nH_{2n+1}]^+Cl^-$, is a mixture of alkyldimethylbenzylammonium chlorides. The alkyl chains have a length of 8 – 18 carbon atoms. According to the European Pharmacopeia 1997, the mean molecular mass should be ca. 354 [49].

The effect of alkyl chain length of benzalkonium chloride on gram-negative and gram-positive bacteria has been tested in a suspension test [50]. The effective concentration against *Staphylococcus aureus* and *Pseudomonas aeruginosa* is shown in Table 6. This test indicates that gram-negative bacteria are less susceptible. The most effective benzalkonium chlorides are compounds in which the alkyl residues have 12 or 14 carbon atoms.

Benzalkonium chloride is used as an active ingredient in surface disinfectants. Its lack of activity against mycobacteria would disallow its use as an instrument disinfectant.

Benzalkonium chloride has low oral toxicity [51]. Because it is effective in low concentration, this agent is frequently chosen as an ingredient for disinfectants to be used in the vicinity of food. However, benzalkonium chloride is inactivated, as are other cation-active compounds, by many anions, including anionic detergents.

Table 6. Concentration of benzalkonium chloride effective within 10 min against *Staphylococcus aureus* and *Pseudomonas aeruginosa*

Chain length	Concentration, ppm	
	Pseudomonas aeruginosa	*Staphylococcus aureus*
C_8	6000	3000
C_{10}	1200	450
C_{12}	120	45
C_{14}	40	15
C_{16}	200	30
C_{18}	1000	450

Didecyldimethylammonium chloride [*2390-68-3*], is an interesting alternative to benzalkonium chloride. Toxicological and ecotoxicological properties have been thoroughly investigated (Lonza AG) with favorable results.

Poly(hexamethylenebiguanide) hydrochloride [*32289-58-0*] is also used as a surface disinfectant and is alleged to be suitable for skin disinfection. This compound has a slow effect and does not meet the practical requirements for prophylactic antiseptics in this respect. Although it is somewhat less effective than benzalkonium chloride (Table 7), it is sometimes used instead of benzalkonium because it is less foam producing under use conditions.

Poly(hexamethylenebiguanide) hydrochloride

Cetylpyridinium chloride [*123-03-5*] is used for treatment of mucous membranes and as throat medicine. Furthermore the substance is applied as preservative due to its excellent bacteria inhibiting property. In this respect it is of some interest that gram-negative bacteria are less sensitive by a factor of 4 than gram-positive bacteria [53]. The substance does not inactivate polioviruses or adenoviruses [54].

Cetylpyridinium chloride

Chlorhexidine [*55-56-1*], a bisbiguanide, is a strong base that is only slightly soluble in water (solubility 0.008 % at 20 °C). It is used worldwide, especially in skin and hand disinfectants, generally in the form of the digluconate, as a bacteriostatic. A group of experts at the German BGA summarized the available results and cer-

Table 7. Required exposure time as determined in suspension test [52]

Microorganism	Exposure time, min			
	A *	A * plus 10 % serum	B **	B ** plus 10 % serum
Staphylococcus aureus	5	5	15	15
Pseudomonas aeruginosa	30	60	15	15
Proteus vulgaris	15	15	60	60
Candida albicans	5	15	15	30

* 0.05 % Benzalkonium chloride.
** 0.05 % Poly(hexamethylenebiguanide) hydrochloride.

tified that chlorhexidine has above all an excellent bacteriostatic efficacy against gram-positive bacteria. The minimum inhibiting concentration is ≥ 1 µg/L. Significantly higher concentrations are given for gram-positive bacteria and fungi (10 to > 73 µg/mL). In the presence of blood or protein the efficacy is reduced by a factor of 100 to 1000 [55].

Chlorhexidine digluconate

4 % solution of chlorhexidine digluconate is frequently used in hand wash lotions. Application of such a lotion leads to ca. 90 % germ reduction, which can be increased to 98 % after 6 applications [56]. However, it does not meet specifications established nowadays in Europe for a hand disinfectant. Under the test conditions of the European Standard EN 1499 for the efficacy testing of hygienic wash preparations it turned out that a logarithmic reduction of 3.1 is reached with a 4 % chlorhexidine solution which is customary in trade. There is no significant difference in the efficacy between this solution and soap [57]. In a multicenter study performed in six European countries which included 28 hospitals it was observed that the rate of wound infection had not been influenced by total body washings with a chlorhexidine-containing detergent the night before operation. In this study more than 2800 patients were included [58]. This result may be regarded in connection with investigations showing that a 0.5 % chlorhexidine solution reduces the number of organisms by only ca. 60 % [59], [60].

Chlorhexidine has bacteriostatic effects at low concentration and, like other cation-active compounds, remains on the skin. These properties suggest a combination of chlorhexidine with alcohol. Preparations containing both agents act rapidly, and the presence of chlorhexidine assures a residual effect.

Chlorhexidine is ineffective against polioviruses and adenoviruses. The effectiveness of a 0.1 % solution against herpes viruses has not yet been established unequivocally [54].

Octenidine [*71251-02-0*], a new cation-active agent, is a bispyridine that was used for the first time in an approved disinfectant in 1987 [61], [62]. It may be even more suitable as a remanent active ingredient than chlorhexidine combined with alcohols because it is more effective and better balanced (Table 8). Residual octenidine, after skin disinfection with an alcohol-based, octenidine-containing preparation, was capable of inactivating micrococci introduced later [63].

Octenidine dihydrochloride

Octenidine has been applied as active agent in a mucous membrane antiseptic since 1990 [64], [65]. Today it is one of the preparations prevalently used in many European countries for the treatment of the urogenital tract, buccal cavity [66], and wounds. Octenidine is absorbed neither through the skin nor through mucous membranes nor via wounds and does not even pass the placental barrier [67].

Other cation-active compounds that are used include polymeric quaternary ammonium salts (Buckman Laboratories or Onyx Chemical Co.), and guanidine [68].

6.6. Amphoteric Compounds

Amphoteric compounds, which are derived from glycine by replacing one amino hydrogen atom with an alkylamine group, exhibit antimicrobial activity. Solutions containing such agents are commercially available under the trade name Tego (Goldschmidt, Essen, Federal Republic of Germany) and have the following basic formula:

$RNH(CH_2)_2NH(CH_2)_2NHCH_2COOH$

Solutions of 1 % are effective within a short period against gram-positive bacteria and to a certain extent against gram-negative bacteria as well [69]. Lipid viruses are also inactivated but hydrophilic viruses, such as the poliovirus, are not [70].

The efficacy of these amphoteric compounds is less affected by a high protein burden than other agents generally are. Therefore, such compounds are well suitable for use in the food industry to disinfect working surfaces and equipment. These compounds have surface-active properties similar to those of quaternary ammonium compounds. They have low oral toxicity [71], and toxicologically significant amounts are apparently not absorbed through the skin.

Table 8. Comparison between octenidine and chlorhexidine determined by the suspension test *

	Effective concentration, %	
	Octenidine dihydrochloride	Chlorhexidine digluconate
Staphylococcus aureus	0.025	>0.2
Escherichia coli	0.025	0.1
Proteus mirabilis	0.025	>0.2
Pseudomonas aeruginosa	0.025	>0.2
Candida albicans	0.01	0.025

* Exposure time 5 min.

6.7. Alkylamines

It has already been known for quite some time that selected alkylamines have antimicrobial properties. Their activity against sulfate-reducing bacteria made them of particular interest for the oil-producing industry. Cocospropylenediamine [*61791-63-7*], e.g., is applied in this area. The importance of these compounds in other fields of disinfection increased after a successful strengthening of their antimicrobial properties by further derivatization and/or improvement of their compatibility [72].

N,N-bis-(3-aminopropyl)laurylamine [*2372-82-9*] has a surprisingly high effect against mycobacteria. This compound can be used instead of aldehydes for formulating tuberculocidal preparations [73]. 1.5 % solutions are capable to kill a great deal of mycobacteria in the presence of 0.5 % bovine albumine.

N,N-bis-(3-aminopropyl)laurylamine

Glukoprotamine [*2372-82-9*], a reaction product of cocospropylene-1,3-diamine and L-glutamine acid is present as a mixture of the amide and the corresponding ammonium salts [74]. Glukoprotamine has a well balanced microbiological effect and also kills mycobacteria. An 0.5 % solution is effective in a germ carrier test at pieces of cotton within 60 min against *Mycobacterium terrae*. Enteroviruses are not inactivated.

Glukoprotamine

The effectiveness of both compounds remains for cocospropylenediamine guanidinium diacetate [*67-63-0*], whereas the mycobactericidal effect is restricted.

Cocospropylenediamine guanidinium diacetate

6.8. Inorganic Compounds

Chlorine. Chlorine [*7782-50-5*] is used in large quantities in some countries and has long been known as a disinfectant. The term chlorine is frequently used rather imprecisely. In the present context, the term refers generally to an aqueous solution of chlorine, hypochlorite, or hypochlorous acid. Occasionally, even chlorine-releasing compounds, such as *N*-chlorosulfonamides (e.g., Chloramin T) or *N*-chloroisocyanuric acid, and their salts are included in this group.

Aqueous solutions of chlorine and hypochlorite are extremely effective against a broad spectrum of microorganisms. Frequently, a concentration of < 1 ppm of available chlorine is sufficient to kill bacteria. Viruses are also inactivated under similar conditions [75]. Higher concentration is required to kill spores and mycobacteria.

Because chlorine is so chemically reactive, contaminants, especially organic substances, rapidly impair its effectiveness, which is one of the reasons that chlorine cannot be used universally for disinfection [76].

Other conditions may also significantly alter chlorine effectiveness. One example is pH. Spores of *Bacillus macerans* were reduced by 99 % in 8.5 min when 15 ppm chlorine was used at pH 6, but 42 min were required at pH 8 [77].

Chlorine is used mainly to disinfect drinking water, swimming pools, and food industry installations. Chlorine for household use or for wastewater treatment is questionable for ecological reasons, as the reaction between chlorine and organic material leads to the formation of undesirable organic chlorine compounds.

Iodine. Like chlorine, iodine [*7553-56-2*] has a broad spectrum of effectiveness. It was used mainly to disinfect wounds, skin, and mucous membranes. However, a number of adverse reactions made its use questionable and led to changes in its mode of application. Adverse reactions include local effects, primarily skin irritation, pain when applied to wounds, and the possibility of sensitization. In addition, systemic reactions, notably those affecting the thyroid gland, are known.

Since the mid-1950 PVP – iodine [*25655-41-8*], (providone – iodine), an iodine – polyvinylpyrrolidone complex with 10 % available iodine is being used instead of the old iodine tincture.

This change in the galenic of the iodine preparation had the effect that some of the abovementioned disadvantages of the iodine tincture were significantly reduced, including sensitization, primary skin irritation, or pain.

Around 1980 it was observed that the PVP – iodine use solutions did not have the same efficacy as diluted test solutions [79], [78]. Very soon it was discovered that this phenomenon was due to the fact that aqueous solutions of 10 % PVP – iodine contain only a few ppm of free iodine [80]. The contents of free iodine increases when diluted with water and in consequence efficacy increases, too. However, at the same time the effectiveness decreases when the PVP – iodine solution is loaded with blood, protein, etc. to an inadmissible point because the contents of free available iodine decreases.

By optimizing the galenics it was possible to increase the level of free iodine even in 10 % PVP–iodine solutions to such a point that even undiluted the desired effect was obtained [81].

The use of PVP – iodine is counterindicated in pregnant women and in newborns because the thyriod gland of a fetus or a newborn is not fully functional.

Like chlorine, iodine kills vegetative bacteria rapidly and effectively in the ppm range [82]. Organic materials severely impair its activity. Spores are inactivated only at high concentration of free iodine and longer contact times are used. The use of PVP – iodine on skin for this purpose is questionable. In addition, PVP – iodine is ineffective against enteroviruses, but is active against lipophilic viruses [83], [84].

Acids and bases. Strong alkali-metal and alkaline-earth hydroxides are occasionally employed for disinfecting excretions or as disinfectants in animal husbandry. The concentration must be chosen carefully so that the hydrolytic reactions of microorganisms as well as of organic contaminants proceed at ambient temperature. The same applies to nonoxidizing inorganic acids like sulfurous acid or SO_2.

Metals. Metals, especially heavy metals, have been used for years because of the so-called oligodynamic effect; that is, they are toxic to

bacteria at low concentration. The metals react with thiol (SH) or amine (NH) groups of enzymes or proteins, a mode of action somewhat different from that of the other active agents and one to which microorganisms may develop resistance. Such resistance may be transmitted by plasmids [85–87].

Only mercury and silver compounds are used currently, and then just for specific applications. For example, silver sulfadiazine [*22199-08-2*] is used as a prophylactic antiseptic ointment for extensive burns. An equilibrium dispersion of colloidal silver with dissolved silver ions can be used to purify drinking water at sea [88].

Phenylmercuric borate [*8017-88-7*] or acetate [*62-38-4*] were used for disinfecting mucous menbranes at an effective concentration of 0.07 % in aqueous solutions [89]. Due to toxicological and ecotoxicological reasons phenylmercury salts are no longer applied nowadays. Nevertheless, surgeons use mercurochrom [*129-16-8*] even today and despite toxicological objections. The benefit, however, may be more an adstringent effect than an antimicrobial one.

7. Toxicology

When the toxicology of disinfectants is evaluated, their widely varying methods of application must be considered. Important factors include the final use concentration, whether direct body contact is intended, and the volatility of the substance with the accompanying danger of inhalation. Because coverage of the many possible conditions would be difficult, the present discussion is restricted to a few general comments, and references to toxicologic studies of the active agents.

Short-chain alcohols are considered safe, provided they are properly applied to skin or small areas. They are not absorbed by the skin. *Phenols* used in disinfectants have commonly been well investigated with regard to their pharmacological toxicological properties. For 2-phenylphenol [*90-43-7*] cancerogenicity and teratogenicity tests are available [90]. Even in the applied high dosages neither cancerogenic nor teratogenic effects were observed. These dosages are significantly and by more than a factor 1000 higher than those amount of substances being applied for hand disinfection (Desderman N). Noteworthy is the fact that phenols are readily absorbed through the skin.

Aldehydes may cause local irritation and may elicit sensitization. A formaldehyde concentration as low as 1 ppm in air irritates the upper respiratory tract and the mucous membrane of the eye. This may be an advantageous warning that the facility needs to be ventilated. When used correctly as a surface disinfectant for washing and scrubbing floors, the maximum concentration attained for a short time is just above 0.1 ppm [91]. Concentrations of formaldehyde that cause mucous membrane carcinomas in animals are not likely be reached when appropriate disinfectants are used properly [92], [93].

Modern preparations containing *active oxygen* are characterized by low volatility. They are a genuine improvement over aldehyde-based preparations, especially considering their broad range of activity. Their acute oral toxicity is low and they cause only mild local irritation.

Cation-active and amphoteric compounds are not readily absorbed through the skin or the mucous membrane. These compounds cause local irritation and are extremely poisonous when administered parenterally [51]. Specific toxic effects have been observed occasionally as, for example, effects of chlorhexidine on hearing and balance [94].

With *iodine*, the systemic effect and the effect on thyroid function are important. With *metals*, central nervous system involvement may be a consideration.

In summary, the toxic properties of the products must be made known by the manufacturers, and proper precautions must be taken by the consumers. If directions for use are followed, most preparations can be handled without presenting any danger.

1. Introduction

Disperse dyes are colorants with low water solubility that, in their disperse colloidal form, are suitable for dyeing and printing hydrophobic fibers and fabrics. Forerunners of the disperse dyes were the ionamine dyes of British Dyestuffs Corp.; these were *N*-methanesulfonic acids of aminoazo or aminoanthraquinone dyes that released the *N*-methanesulfonic acid group in the dyeing process and, thereby, precipitated as disperse dyes on the acetate fibers. The understanding of this mechanism in 1923 initiated the development of genuine disperse dyes. British Celanese and British Dyestuffs Corp. were the first companies to introduce these dyes into the market, under the names SRA dyes and Dispersol dyes, respectively, for coloring acetate fibers. The SRA dyes were dispersed with sulforicinoleic acid [*8002-33-3*], and the Dispersol dyes, with soap or Turkey-red oil [1].

From 1924 to 1930, products of other companies appeared on the market, initially as pastes; later, when the materials could be dried successfully without interfering with their dispersibility, they were also marketed as powders. Since 1950, the production of disperse dyes has increased sharply, closely following the growth in worldwide production of synthetic fibers, especially polyester [poly(ethylene terephthalate)] fibers, production of which has grown steadily from ca. 2×10^6 t/a in 1970 to ca. 16×10^6 t/a in 1999 [2].

Furthermore, new dyeing processes necessitated the development of special disperse dyes. For instance, dyes characterized by special ease of sublimation are preferred for transfer printing [3]. The demand for new fastness properties such as thermomigration fastness and automotive light fastness [4–7] also led to new dyes, as has the ongoing pressure on market prices.

Models for the dyeing of polyester fibers with disperse dyes have been developed [8]. When the dye is applied from aqueous medium, it is adsorbed from the molecularly dispersed aqueous solution onto the fiber surface and then diffuses into the interior of the fiber. The following parameters determine the rate of dyeing and, to some extent, the leveling properties: (1) the dissolution rate during the transition from the dispersed crystalline state of the dye into the molecularly dispersed phase, and (2) the diffusion rate at the fiber surface and, especially, in the interior of the fiber. The rates of both processes vary with temperature.

Differences in geometry and polarity of the dye molecules can lead to wide variations in these finishing or dye-specific properties and can

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a08_565

have a marked effect on the absorption characteristics of all dyes, irrespective of whether single-component or combination dyeing processes are used. For instance, uneven dyeing may occur when an unequal distribution of particle size results in insufficient dispersion stability and, thus, crystal growth and precipitation at the substrate surface.

Dye Classes. Industrially applied disperse dyes are based on numerous chromophore systems. Approximately 60 % of all products are azo dyes and ca. 25 % are anthraquinone dyes, with the remainder distributed among quinophthalone, methine, naphthalimide, naphthoquinone, and nitro dyes [10]. Azo dyes are employed to create almost the entire range of shades; anthraquinone derivatives are used for red, violet, blue, and turquoise. The remaining dye classes are used mainly to produce yellow shades. In this article, the disperse dyes are grouped according to their chemical constitution rather than their color properties. Production methods are discussed only briefly; details are given in the specific dye-related articles, e.g., → Anthraquinone Dyes and Intermediates, → Azo Dyes.

Of the huge range of disperse dyes published in journals and patents, only those are mentioned which have attained some industrial importance. Fastness properties and often also the structures are disclosed in the Colour Index [11].

2. Anthraquinone Dyes

The brilliant red, blue, and turquoise anthraquinone dyes have great industrial significance. The most important red shades are produced by alkyl or aryl ethers of 4-amino-1,3-dihydroxyanthraquinone [*81-51-6*] (**1**).

1
R = alkyl, aryl

Blue and turquoise dyes also play a dominant role. The most important blue dyes come from ring- or N-substituted derivatives of the two isomers of aminodihydroxyanthraquinone (**2** and **3**).

2
X = NH_2, NO_2

3

Turquoise shades are obtained from derivatives of 1,4-diaminoanthraquinone-2,3-dicarboximide [*128-81-4*] (**4**).

4
R = alkyl

In comparison to azo dyes of similar shades, the anthraquinone derivatives are frequently characterized by greater clarity and better stability against hydrolysis and reduction. The anthraquinone disperse dyes are described in detail under → Anthraquinone Dyes and Intermediates.

A serious handicap of anthraquinone dyes is their poor dyeing strength, which is indicated by a low molar extinction coefficient ε. The ε value usually has a range of 12 000 – 34 000 L mol^{-1} cm^{-1} for anthraquinone dyes, depending on the shade, whereas azo dyes of similar shade attain ε values of 30 000 – 84 000 L mol^{-1} cm^{-1}. This is the reason why disperse anthraquinone dyes have been increasingly displaced by azo dyes. Reviews of this ongoing process are given in [12], [13]. Research on new dyestuffs has therefore been concentrated on nonanthraquinoid dyestuffs. The only exception to this is the brilliant blue dye **5** [14].

5
[*93686-63-6*] [14]

3. Azo Dyes

Azo dyes represent the largest group of disperse dyes for two reasons: (1) the ease with which an extraordinary number of molecular combinations can be generated by varying the diazo and the coupling components and (2) the relatively simple process by which the dyes can be produced. With this class of dyes, manufacturers can respond much more easily to customers' and end users' requests for special shades and fastness characteristics.

In the following survey, the most important disperse azo dyes are divided into mono- and disazo types; then each of these classes is subdivided according to the diazo and the coupling components. The diazo component is further subdivided where appropriate into aromatic and heteroaromatic amines.

3.1. Monoazo Dyes

About 50 % of all disperse dyes are monoazo dyes, which thus represent the largest single group [10]. Relatively simple syntheses enable a range of shades from greenish yellow to cyan to be produced with this chromophore system.

3.1.1. Aromatic Amines as Coupling Components

Carbocyclic Aromatic Amines as Diazo Components. Dyes of structure **6**, in which aminobenzenes are the coupling components, predominate.

6
D denotes an aromatic or heterocyclic group of the diazo component

Of all the disperse azo dyes, this class has the greatest economic importance. Commercial products are most often represented by structure **7**, in which 4-nitroaniline [*100-01-6*] and its substituted derivatives constitute the diazo component.

7
X, Y = H, Cl, Br, CN, NO_2, CH_3SO_2
A = H, CH_3, Cl, NHCOR
B = H, CH_3O, C_2H_5O, Cl
R^1, R^2 = H, CN, OH, OCOR, COOR, aryl (R = alkyl)

The most important diazo components are 4-nitroaniline [*100-01-6*], 2-chloro-4-nitroaniline [*121-87-9*], 2-cyano-4-nitroaniline [*17420-30-3*], 2,4-dinitroaniline [*97-02-9*], 2,6-dichloro-4-nitroaniline [*99-30-9*], 2-bromo- [*1817-73-8*] and 2-chloro-4,6-dinitroaniline [*3531-19-9*], and 2-bromo-6-cyano-4-nitroaniline [*17601-94-4*]. The coupling components are derived from aniline, 3-aminotoluene [*108-44-1*], 3-chloroaniline [*108-42-9*], 3-aminoacetanilide [*102-28-3*], and 3-amino-4-alkoxyacetanilide by *N*-alkylation.

This type of dye quickly became important for dyeing acetate fibers. It has been adapted to the requirements of polyester fibers and of different dyeing processes, mainly by varying the substituents R^1 and R^2 [15–18].

For example, the β-hydroxyalkyl groups (R^1 and/or R^2 = OH), typical for many acetate dyes, were replaced by less hydrophilic groups such as CN, OCOR, and COOR, which enhanced the affinity for polyester fibers and, in many instances, the fastness to light and sublimation [10], [19].

The shade of dyes with formula **6** depends largely on the substituents X, Y, A, B, R^1, and R^2. If the coupling component is held constant and X = H, variation of Y results in a bathochromic shift, which increases in the following order: H, Cl, NO_2, CH_3SO_2, CN.

If X and Y $\neq$ H, the situation is more complicated because of possible steric effects on the azobenzene system [20]. For example, if X = Y = Cl, steric hindrance prevents a planar alignment of the azobenzene molecule, which leads to a hypsochromic shift with simultaneous loss of clarity. This effect is exploited in the industry to produce brown shades. Cyano groups exert no steric effects, and the strongest bathochromic shifts can be obtained by using X = Y = CN; X = CN, Y = NO_2; and X = CN, Y = CH_3SO_2. When the diazo component is held

constant, a bathochromic shift occurs which increases in the order A = Cl, H, CH_3, NHCOR. The most extreme bathochromic effect is obtained when A = NHCOR and B = OR. In combination with 2-bromo- [*1817-73-8*] or 2-chloro-4,6-dinitroaniline [*3531-19-9*] as the diazo component, commercially important navy blue dyes are obtained; of all the monoazo dyes, these are produced in the largest quantity.

The significant influence of R^1 and R^2 on color is quite surprising because these substituents are not components of the chromophore system. Ester and, especially, cyano groups in these positions cause a distinct hypsochromic shift [10].

A few examples of the many dyes from this series that are used to dye polyesters are listed below:

Orange [*4058-30-4*] [21]

Red, C.I. 11114, [*12223-39-1*] [22]

Navy blue, C.I. 11345, [*3956-55-6*] [23]

Disperse Blue 165 [*41642-51-7*] [24]

Representatives of this class are also suitable for dyeing cellulose triacetate [*9012-09-3*]. However, sufficient lightfastness is not obtained on synthetic polyamides [10].

Other industrially important 2,6-dicyanoazo dyes are obtained by using diethyl-*m*-toluidine and 3-diethylaminophenylmethansulfonamide [*52603-47-1*] as coupling components (see **8** and **9**, respectively).

8
Disperse Blue 366 [*84870-65-5*] [25]

9
Red [*68385-96-6*] [26]

By mixing the reddish blue Disperse Blue 366 with Disperse Blue 165 [27] or heteroarylazo dyes [28], technically equivalent replacement products [13] for the anthraquinoid Disperse Blue 56 were obtained. The red dye **9** has been similarly used as a substitute [12] for the anthraquinoid Disperse Red 60.

Heteroaromatic Amines as Diazo Components. Developments in this field started with the finding that 2-amino-5-nitrothiazole [*121-66-4*] [29] gave bright blue shades of reasonable fastness in azo dyes for cellulose acetate (e.g., **10**, [30]). Because of their good dischargeability but limited fastness properties, these dyes were also used on polyester. The importance of this class of dyes has diminished since some of them have been found to have sensitizing properties (see Chap. 6).

10
Blue [*70865-21-3*] [31]

2-Amino-6-nitrobenzthiazole [*6285-57-0*] and 2-amino-5,6- or 6,7-dichlorobenzthiazole [*24072-75-1*], [*25150–27-0*] are widely employed to give scarlet to ruby shades because of their facile accessibility by ring closure of 4-nitrophenylthiourea [32] or 3,4-dichlorophenylthiourea, respectively. In the latter case the resulting mixture of isomers is directly utilized for diazotization and transformed into the mixture of dye isomers **12**.

11
[*68133-69-7*] [33]

12
[*117541-97-6*], [*117541-98-7*] [34–36]

The red dye **13** is an example for the use of the methanesulfonyl group as an acceptor in azo dyes.

13
Red [*63467-01-6*] [37]

2-Amino-5-ethylsulfanyl-1,3,4-thiadiazole [*25660-70-2*], accessible by alkylation of bithiourea with diethyl sulfate and ring closure [38], is suitable for the manufacture of bright reds, e.g., **14**.

14
Red [*63134-15-6*] [39]

2-Amino-4,5-dicyanoimidazole [*40953-34-2*] can be made by reaction of diaminomaleonitrile with cyanogen chloride. By coupling with aniline couplers and alkylating the resultant azo dye precursor bright reds such as **15** are obtained.

15
Red [*86772-44-3*] [40]

3-Amino-5-nitro-2,1-benzisothiazole is manufactured by thiolysis of 2-amino-5-nitrobenzonitrile and oxidative ring closure. With aniline coupling components, shades from navy to greenish blue are obtainable (e.g., **16** and **17**).

16
Disperse Blue 148 [*52239-04-0*] [41]

17
Blue [*105076-77-5*] [42]

Since the first appearance of thienylazo dyes like Disperse Green 9 in the early 1970s, this field has been intensely exploited. The interest originates from the fact that thienylazo dyes are nearly 100 nm more bathochromic than their carbocyclic counterparts (cf. Disperse Green 9 and **18**) and exceed these in the molar extinction coefficient and hence also in dyeing strength.

Disperse Green 9 [*58979-46-7*] [43]
$\lambda = 644$ nm $\varepsilon = 87\,400$ L mol^{-1} cm^{-1} [12]

18
$\lambda = 545$ nm $\varepsilon = 46\,000$ L mol^{-1} cm^{-1} [44]

Furthermore, the Gewald reaction [45] opened a simple and economic access from aliphatic reactants to aminothiophenes that were formerly only accessible from multistep reactions [46] (see, e.g., the dye **19**. For example, 2-amino-3-carbethoxy-5-nitrothiophene, a precursor for the dye **20**, can be prepared by reaction of 1,4-dithiane with ethyl cyanoacetate and subsequent nitration.

19
Blue [*42783-06-2*] [47]

20
Blue [*210758-04-6*] [48]

Whereas the blue dyes **19** and **20** are claimed to have good thermomigration fastness, **21**, **22**, and **23** have superior pH stability and are proposed as substitutes for bright anthraquinone blues.

21
Blue [*104366-25-8*] [49]

22
Blue [*122063-39-2*] [50]

23
Blue [*167940-11-6*]

By combination of the thiophene diazo moiety with a diaminopyridine coupler, the hue is shifted to a bright red with good lightfastness (**24**).

24
Red [*107815-88-3*] [51]

The chemistry and physics of azo dyes based on heterocyclic amines has been surveyed in many reviews [52–54]

Aminonaphthalenes as Coupling Components. In comparison to aminobenzenes, aminonaphthalenes have played only a minor role as coupling components for disperse dyes and are encountered in only a few industrial appli-

cations, e.g., **25** for coloring of cellulose acetate fibers.

25
Blue [*69828-87-1*] [55]

3.1.2. Aromatic Hydroxy Compounds as Coupling Components

Dyes with aromatic hydroxy compounds as the coupling components, of which Cellitone Fast Yellow G is a representative example, have been used many years to dye acetate fibers. Its use has been questioned for ecological reasons (see Chap. 6). For application to polyesters, sublimation fastness has been enhanced by increasing the size of the molecule.

Disperse Yellow 3, C.I. 11855 [*2832-40-8*]

When 2-hydroxynaphthalene [*135-19-3*] and its derivatives are used as coupling components, clear orange (e.g., **26**) and red shades result. Their commercial importance is low.

26
Orange [*17947-32-9*] [56]

The chemistry of 4-hydroxynaphthalimides as coupling components has mainly been investigated in Japan. Brilliant reds with good fastness properties are obtainable (e.g., **27**).

27
Red [*42357-98-2*] [57]

3.1.3. Heterocyclic Compounds as Coupling Components

The importance of the formerly widespread pyrazolone, aminopyrazole, and 4-hydroxyquinolone based yellow azo dyes has greatly diminished with the advent of the tinctorially superior and therefore more economical pyridone azo dyes. Only a few examples have survived in special applications such as for dyeing of acetate fibers. Examples are Disperse Orange 56 and Disperse Yellow 5.

Disperse Orange 56 [*67162-11-2*] [58]

Disperse Yellow 5 [*6439-53-8*]

By reaction of ethyl acetoacetate with cyanoacetamides, pyridones are easily accessible. By selection of suitable substituents in the diazo components, shade and fastness properties and build up can be steered (e.g., **28**, **29**, **30**, **31**, and Disperse Yellow 211).

28
Greenish Yellow [*59312-61-7*] [59]

29
Greenish Yellow [*37781-00-3*] [60]

30
Greenish Yellow [*88938-37-8*] [61]

31
Greenish Yellow [*83249-52-9*] [62]

Disperse Yellow 211 [63]

Chlorination of 2,6-dihydroxy-3-cyano-4-methylpyridine with phosphorus oxychloride and successive reaction with amines yields 2,6 diaminopyridines. With these coupling components brilliant orange and red dyes with excellent lightfastness are obtained (e.g., **32**, [4]).

32
Red [*63833-78-3*] [64]

3.1.4. Production of Monoazo Dyes

The production of monoazo disperse dyes by diazotization and coupling is described in detail under → Azo Dyes. Additional chemical treatment subsequent to synthesis of the azo compounds is performed only rarely.

Frequently, weakly basic amines, such as negatively substituted 4-nitroanilines or aminoheterocycles, must be diazotized. These reactions require concentrated sulfuric acid, phosphoric acid (85 wt %), glacial acetic acid, propionic acid, or mixtures of these acids as the reaction medium, with nitrosylsulfuric acid as the reagent. On an industrial scale, this reaction is conducted preferably in enameled, stirred vessels. Whenever the stability of the amine or the diazonium salt permits, diazotization is carried out in concentrated sulfuric acid at slightly elevated temperature (10 – 40 °C). With regard to safety, factors such as temperature and concentration must be controlled carefully to avoid explosion [65].

The sulfuric acid diazotization mixture is generally added directly to the ice-cold solution or suspension of the coupling component. If the diazonium salt is stable in dilute sulfuric acid, the diazotization mixture may first be quenched with ice, possibly clarified, and only then combined with the coupling component.

Strongly negatively substituted 4-nitroanilines, such as 2,4,6-trinitroaniline [*489-98-5*], 2,4-dinitro-6-cyanoaniline [*22603-53-8*], 2-methanesulfonyl-4-nitro-6-cyanoaniline, and 2,6-dicyano-4-nitroaniline [*20033-48-1*], are difficult to diazotize, and their diazonium salts tend to decompose extensively during the coupling process [15]. This results in diminished yields and loss of clarity of the dyes.

These difficulties may be avoided if 2-halogenoazo dyes, preferably 2-bromoazo dyes, are generated first, and the halogen is then exchanged for the NO_2 or CN group. These copper-catalyzed reactions proceed especially smoothly in dipolar aprotic solvents such as ethylene glycol monoalkyl ethers, dimethylformamide, dimethyl sulfoxide, or *N*-methylpyrrolidone, and they occur under considerably milder conditions than those in the starting amine [66–68]. In this process, the bromo – cyano exchange yields clear blue polyester dyes (see formula **33**) of a shade which, formerly, could only be obtained by using anthraquinones.

33
X = CN, NO_2

By modification of the substituent in the 4-position of the diazo component, this process yields further 2,6-dicyanoazo dyes, for example, 4-methyl- or 4-bromo-2,6-dicyano derivatives, where the basic diazo component is otherwise difficultly accessible. In this way clear red shades on polyester can be obtained.

3.2. Disazo Dyes

About 10 % of all disperse dyes are disazo compounds [10]. Even the simplest hydroxy disazo dyes, such as 4-aminoazobenzene coupled to phenol and 4-aminoazobenzene coupled to *o*-cresol, have good affinity for polyester fibers and yield lightfast reddish yellow hues. However, these shades are frequently less bright than those obtained with monoazo dyes.

The introduction of an alkoxy group into the central benzene ring causes a distinct shift toward orange. A similar bathochromic effect is obtained by replacing this benzene with naphthalene.

Substitution of the first benzene nucleus by electron acceptors also causes bathochromic shifts. Disazo dyes of this type such as **34** are frequently incorporated as components of black mixtures.

34
Orange, C.I. 26077 [*19800-42-1*] [69]

The simplest route to disazo dyes is by using *p*-aminoazobenzene [*60-9-3*]. As *p*-aminoazobenzene has been classified in the EU as carcinogenic, the use of derived disazo dyes like Disperse Red 151, Disperse Yellow 7, Disperse Yellow 23, and Disperse Yellow 56 has diminished.

Many disazo dyes with derivatives of aniline as the terminal component have been described in the literature, but only a few have become industrial products. Replacement of the central benzene by heterocycles such as thiazole or thiophene causes marked bathochromic shifts.

36
Blue [*87606-56-2*]

4. Other Chromophores

Quinophthalones. 3′-Hydroxyquinophthalone [*7576-65-0*] is employed extensively in a number of product lines used to dye synthetic fibers in greenish yellow hues with good lightfastness and generally sufficient sublimation-fastness. Suitable substitution in the phthalic acid residue or the quinoline nucleus may improve thermosetting fastness [71]. For synthetic methods, see → Methine Dyes and Pigments.

Disperse Yellow 64 [72]

37
Yellow [*75216-43-2*] [73]

Methine Dyes. Condensation products of 4-dialkylaminobenzaldehydes with cyanoacetic esters have long been used to dye acetate fibers. Brilliant greenish yellow dyes with excellent lightfastness are obtained on polyester fibers with the corresponding condensation products of malonodinitrile. The sublimation fastness of this dye type can be improved by introducing suitable substituents into the alkyl residue of the amino group or by doubling the molecular size (**38**) [16], [74].

38
Yellow [*25857-05-0*] [75]

Brilliant blue dyes such as **39** are produced from aminobenzaldehydes and benzothiophene derivatives.

39
Blue [*74239-96-6*] [76]

By condensation of 2-hydroxy-4,4′-diethylaminobenzaldehydes with hetarylacetonitriles, 3-heteroaryl-7-diethylaminocoumarins such as **40** and **41** are obtained, which dye polyester fibers fluorescent yellow with a strong green tint.

40
Yellow [*27425-55-4*] [77]

41
Brilliant Yellow [*35773-43-4*] [78]

Further condensation with malonodinitrile results in fluorescent red dyes such as **42**.

42
Red [*53272-39-1*] [79]

Oxidative cyanation of yellow 3-heteroaryl-4*H*-7-diethylaminocoumarin dyes such as **40** and **41** introduces a 4-cyano group and yields fluorescent red dyes [9]. For example, treatment with NaCN followed by Br_2 gives **43**.

43

By elongation of the methine chromophore even brilliant blues such as **44** can be produced. Because of limited fastness properties, this interesting new dye could not yet pose a threat to anthraquinone dyes.

44
Brilliant blue [*108948-36-3*] [80]

Condensation of mandelic acids and hydroquinone, followed by oxidation, results in yellow to red polyester dyes [81]. This new chromophore shows excellent thermomigration fastness and has been frequently varied to cover all red shades (e.g., **45**) and to improve build up.

45
Red [*79694-17-0*] [81]

Naphthalimide Dyes. Derivatives of 4-aminonaphthalimide were used initially to dye acetate fibers. For polyesters, condensation products of 1,8-naphthalenedicarboxylic acid [*518-05-8*] or 1,4,5,8-naphthalenetetracarboxylic acid [*128-97-2*] with 1,2-diaminobenzenes are used.

49
Yellow [*15220-29-8*]

Indigo Dyes. Whereas indigo itself is not suitable for exhaustion dyeing of polyester, thioindigo gives fast brilliant red shades in pale to medium depth [82].

Nitro Dyes. 2-Nitrodiphenylamines are readily obtained by condensation of derivatives of 2-nitrochlorobenzene [*88-73-3*] with suitable aromatic amines. Because of their accessibility and good lightfastness, these dyes became very important for dyeing cellulose acetate and, more recently, have gained a solid position as disperse dyes for polyester fibers. This is especially true for the reaction product of 1 mol of 3-nitro-4-chlorobenzenesulfonyl chloride [*97-08-5*] and 2 mol of aniline. An exhaustive review of the constitution and color of nitro dyes is given by Merian [83]. The yellow nitroacridones may also be classified in this group.

50
Yellow, C.I. 10338 [*5124-25-4*]

51
Yellow [*19309-55-8*] [84]

5. Production of Disperse Dyes

Chemical synthesis produces dyes of varying particle size. When the dyes are applied in this form, uneven and spotty dyeing results, and the dyeing process may be slow and frequently accompanied by incomplete absorption [85]. To assure high yield, good reproducibility, and faultless dyeing and printing in commercial use, especially when densely woven fabric or wound material is involved, the dye must be applied as a fine dispersion that is stable under the process conditions.

Therefore, the first requirement is that the dye itself be present in a stable crystal modification that does not change during application. If such a modification cannot be obtained by synthesis, attempts must be made to generate it by thermal posttreatment, for instance, by heating the dye in an aqueous suspension in the presence of nonionic detergents.

The eventual dispersion process consists of grinding the moist dye, generally in a ball, bead, or sand mill, in the presence of dispersing agents. Since the dyeing rate depends on particle size, the aim is to reduce the particle size to $< 1\ \mu m$. A narrow particle-size distribution is important to minimize recrystallization during storage and application.

The dispersion agents used are primarily ligninsulfonates (sulfite cellulose liquors); condensation products of naphthalene, sulfuric acid, and formaldehyde; condensation products of *m*- and *o*-cresol, formaldehyde, and 2-hydroxynaphthalene-6-sulfonic acid [*93-01-6*]; or mixtures of these products [85]. Literature on dispersing agents is relatively scarce [86–88].

Difficulties in the production of disperse dyes may be encountered, for example, in grinding or drying dyes with low melting points. Therefore, only dyes that have a melting point $> 120\,°C$, and preferably $> 140\,°C$, should be used. Disperse dyes are sold either as aqueous pastes obtained by grinding or as powders obtained by gentle drying of the paste. Powders are generally produced by spray drying. Important requirements for industrial products are the storage stability of the paste and the ease with which the powder can be redispersed in water. The actual dye content of commercial products is generally 20 – 40 % for pastes and 20 – 50 % for powders.

6. Toxicology and Ecotoxicology

Ecotoxicology. Due to their poor water solubility (< 1 mg/L), disperse dyes have low acute ecological impact. Especially the acute toxicity to aquatic life is generally low. Nevertheless, according to the European chemicals legislation disperse dyes are classified as substances, that "may cause long-term adverse effects in the aquatic environment" [89], [90], because they are not easily biodegradable and suspected as

being potentially bioaccumulative due to their hydrophobicity.

In practice, unfixed disperse dyes discharged from spent dye baths to wastewater treatment plants are easily eliminated by coprecipitation with the sewage sludge and may be anaerobically degraded in the digestion process.

Most commercial disperse dyes are formulated with naphthalene sulfonate or lignosulfonate dispersing agents. These dispersants are completely discharged with the spent dyebath. They have poor biodegradability and will pass the treatment plants to a notable extent. Although not harmful to aquatic life, these dispersants contribute to the persistent COD load of the wastewater. Recently, disperse dyes containing highly effective biodegradable dispersants were brought onto the market (Dianix ECO types [91]).

Toxicology. Disperse dyes generally have low mammalian toxicity as a result of their low solubility and bioavailability. Like any organic chemical, disperse dyes, mostly as powder formulations, must be handled according to good industrial working practice [92].

Some specific azo-type disperse dyes, which contain theoretically azo-cleavable carcinogenic amines, are banned in some countries, e.g. Germany, for the dyeing of consumer goods such as garments [93]. Examples of this class which seem to be still on the market presently are C.I. Disperse Orange 60, C.I. Disperse Red 221 and C.I. Disperse Yellow 218 [94].

Some disperse dyes occasionally have caused clinically documented contact allergies in consumers wearing polyamide hosiery, leggings, and similar disperse-dyed articles. On polyamide, cellulose acetate, and elastane fibers, disperse dyes exhibit poor wet fastness properties and hence can migrate onto the skin of the consumer and potentially elicit allergenic reactions in sensitized persons [95].

Nine generic disperse dyes with epidemiologically proven sensitizing properties are intended for a total ban in the dyeing of garments by the EU: C.I. Disperse Blue 1, Disperse Blue 3, Disperse Blue 35, Disperse Blue 106, Disperse Blue 124, Disperse Yellow 3, Disperse Orange 3, Disperse Orange 37/76, and Disperse Red 1 [96]. These species are already banned by the most important private ecological standard, namely, Oeko-Tex Standard 100 [97], and company related eco standards.

7. Trade Names

Disperse dyes are used to dye cellulose 2,5-acetate, cellulose triacetate, synthetic polyamides, and to a lesser degree, polyacrylonitrile and polypropylene. Their major application is clearly for dyeing polyesters.

Since only a few individual dyes have satisfactory properties for all synthetic fibers, many dye producers are offering separate lines for individual fibers as well as for various application methods. The following list includes the best-known disperse dye lines for dyeing polyester fibers:

Bucron (Blackmann-Uhler)
Dianix (DyStar)
Dispersol (BASF)
Foron (Clariant)
Kayalon Polyester (Nippon Kayaku)
Miketon Polyester (Mitsui Toatsu)
Palanil (BASF)
Serilen (Yorkshire)
Sumikaron (Sumitomo)
Terasil (Ciba Specialities)

As a result of closing of production, merging of producers, or renaming of disperse dye ranges the list of global players has greatly diminished, whereas local producers especially in the Far East, have grown. Parallel to this development, concentration on major products and streamlining of ranges has reduced the number of individual colorants.

8. Economic Aspects

From 1975 to 1998 the share of polyester fibers in world man-made fiber production has nearly doubled from ca. 30 to almost 60 %. Production of disperse dyes has accompanied this tremendous growth. In 1997 disperse dyes accounted for ca. 18 % of the total world market for textile dyes of 800 000 t/a and ca. 20 % of the turnover of € 6×10^9.

1. Terminology

If two or more phases that are insoluble or only slightly soluble are finely distributed in one another, the term *disperse system* or, more simply, *dispersion* is used. The continuous, or external phase is termed the *dispersion phase* or *dispersion medium,* while the substance (finely) distributed in it is termed the *internal phase* or *dispersed phase.* The preparation of a dispersion is known as *dispersing,* and the products that are able to promote or stabilize the formation of a dispersion are termed *dispersants* [1–3].

Table 1 lists disperse systems on the basis of the state of aggregation of the external and internal phases [4], [5]. Unlike true solutions, the disperse systems are termed *sols,* and this term is qualified on the basis of the dispersion medium used. If the latter is a gas, the sol is described as an *aerosol;* if liquids are used, the sol is described as a *lyosol;* and if a solid is used, the sol is described as a *solid sol.* In describing the solid sols, the establishment of concepts is difficult since there are no particles in the sense of kinetic entities and often not even any clearly defined interfaces.

Literature often fails to make a precise distinction between *dispersions* and *suspensions.* In describing disperse systems, the term *dispersion* should be used as the generic term, with solid/liquid systems then being described as *suspensions.*

Several peculiar terms persist in general use. The term "photographic emulsions" is used even though solid silver halide particles are finely distributed in the gelatine, so that the term "suspensions" would be more correct. The term "dispersant" is applied to products or product mixtures that are used to disperse solids finely in a liquid phase, whereas on the basis of Table 1 the term "suspension agent" is more appropriate. Paints in which binders and pigment particles are stably dispersed in an aqueous phase are described in English use as "emulsion paints."

The mean particle diameter determines the degree of dispersion (Table 2) [5]. The particle size is decisive in determining the behavior

Table 1. Disperse systems

Disperse systems (sols)	Dispersion medium (continuous phase)	Dispersed substance (dispersed phase)	Description
Aerosols	gas	gas	
	gas	liquid	mist
	gas	solid	smoke
Lyosols	liquid	gas	foam
	liquid	liquid	emulsion
	liquid	solid	suspension (dispersion)
Solid sols	solid	gas	solid foam
	solid	liquid	solid emulsion
	solid	solid	solid suspension

of a disperse system under the action of gravity. If the particles are colloidal, they are kept in suspension by Brownian movement. However, this is not the case in disperse systems containing coarse particles, which must be stabilized by adding stabilizers.

Table 2. Degree of dispersion [2]

Dispersion	Mean particle diameter, m
Coarsely disperse	$> 10^{-6}$
Colloidal	10^{-6} to 10^{-9}
Highly disperse	$< 10^{-9}$

In most disperse systems, the particle size is variable and Figure 1 shows the particle size distribution F. If the particle size distribution curve is very narrow (A), the system is said to be monodisperse [6], but if the distribution curve is sufficiently wide, the system is termed polydisperse (B). If the concentration of monodisperse spherical particles is sufficiently high, the configuration of the internal phase is one of closely packed spheres. Since the areas of contact between spheres of equal size are greater than those of spheres of different size, the viscosity of monodisperse systems is higher than that of polydisperse ones [7]. In the case of polydisperse systems, achievement of a higher volume fraction of particles is also possible. For an account of the rheology of concentrated suspensions, see [8].

The goal of particle size depends on the particular application. For the manufacture of ionexchanger beads, a mean bead diameter of ca. 1 mm is desirable, while for microemulsions the particle diameter is about 10^{-8} m [9].

The energy required to produce a dispersion increases with increasing division of the particles because their surface area dS increases. The energy is proportional to the work dW which has to be performed. The proportionality factor is the interfacial tension γ between the phases to be dispersed:

$$\mathrm{d}W = \gamma \mathrm{d}S \tag{1}$$

As γ decreases, so does the energy that must be expended to produce a dispersion. For this purpose chemicals – the dispersants that lower the interfacial tension of the phases to be dispersed – are added to a disperse system.

Figure 1. Particle size frequency F as a function of the particle diameter d
A) Monodisperse emulsion B) Polydisperse emulsion

Once produced, particles must be protected against immediately coalescing again. The added dispersing agents, such as emulsifiers and ionic and nonionic surfactants, as well as those dispersants that consist of macromolecules and polyelectrolytes, not only promote dispersion during the preparation of a disperse system, but also make a decisive contribution to stabilizing the particles produced [10]. They create barriers that counteract the natural tendency of individual particles to coalesce again. Thickening agents that increase the viscosity of disperse systems are often added to maintain these barriers.

2. Production of Disperse Systems

The economic advantage, which is associated with the dilution of an active substance in a dispersion, as well as the safety of using aqueous systems rather than the pure active substance of its solution in an organic solvent, has provided a considerable stimulus for the production and application of disperse systems. In principle, there are two methods of producing disperse systems [3]: (1) *condensation,* in which the disperse phase is built-up from atomic or molecular units, and (2) *fine division,* in which coarse particles are reduced in size.

There are many examples of condensation, such as the production of metal sols [11], of pigments with a precisely defined crystal size and shape or the production of latices by emulsion polymerization (→ Emulsions).

In the case of fine division, the energy required to produce a dispersion may be introduced into the system mechanically, chemically, electrochemically, or electrically.

Gases, liquids, or solutions that are not overly concentrated may, e.g., be atomized or sprayed. Liquid phases may also be nebulized [12], [13]. A number of emulsifying machines have been developed for incorporating liquids into aqueous phases; see also → Emulsions. Solids generally must be comminuted mechanically before being introduced into another phase [14], [15], and suitable machines such as mills [16] or ultrasonic generators [17] are used. Finely divided solids are then incorporated in the external phase by stirring or kneading.

A number of studies have been made of the dispersion of particles in shearing fields [16] and in turbulent flows, without any standard theory of mechanical dispersion emerging. The difficulty of arriving at results of fundamental importance is demonstrated by the work of Koglin, Pawlowski, and Schnöring [18].

Despite the existence of machines to produce disperse systems, natural or synthetic dispersants are used which reduce, or almost completely replace, the required mechanical energy, → Emulsions.

3. Stabilization of Disperse Systems

[5], [9], [10], [19–23]

Particles that are dispersed in a dispersion medium are attracted by van der Waals forces. On the other hand, these particles are repelled by electrostatic forces, steric interactions, and Born and solvation interactions. The latter two forces only have a short range. If the forces of attraction dominate, the particles coalesce. If the forces of repulsion dominate, the particles can move freely and a more or less stable system results.

3.1. Attraction Forces

Calculation of van der Waals forces is only possible by using quantum mechanics. The interaction between particles having different geometries in vacuo or in a specified medium has been calculated, using the polarizability of the molecules or the dielectric constants of the phases as starting points [24].

Thus, for example, the following relationship for the energy of interaction V_a has been cited for the special case of similar spherical particles in vacuo [25]:

$$V_a = -(A/12)(a/d) \tag{2}$$

where a is the particle radius, d is the distance between two particle surfaces, which must be distinctly less than a ($d \ll a$), and A is a material constant which is known as the Hamaker constant. The force is obtained by differentiating V_a with respect to d. If the particles are contained in a liquid, a corrected Hamaker constant A_k is approximately valid:

$$A_k = \left(\sqrt{A_{11}} - \sqrt{A_{22}}\right)^2 \tag{3}$$

where A_{11} and A_{22} are the Hamaker constants of the dispersed substance and the dispersion medium, respectively. A_k becomes small if the difference in Eq. (3) decreases; i.e., the attractive forces between dispersed particles can be reduced in two ways: They approach zero (1) if the substance to be dispersed and the dispersion medium have similar Hamaker constants or (2) if the auxiliary agent that is used has a Hamaker constant equal to that of the dispersion medium.

When the particles are enveloped in a solvating layer, the enveloped particles more or less acquire the Hamaker constant of the external phase [26–28]. In this connection hydrate formation of dispersants in aqueous systems is significant [29–31]. Some Hamaker constants are listed in [32]. The Hamaker constants vary with distance since the coupling between the electron oscillators decreases continuously as the distance between them increases [24].

3.2. Repulsion Forces

3.2.1. Electrostatic Interaction

The electrostatic charging of particles dispersed in liquids may occur as a result of the following processes:

1) Rubbing of the particles against each other or against walls of the equipment
2) Dissociation of ionic groups at the surface of the particles
3) Adsorption of ions or oriented dipoles from the dispersion medium on the dispersed particles
4) Adsorption of ionic surfactants on hydrophobic particles
5) Ion exchange between ions of the internal and external phases
6) Difference in the solubility of oppositely charged ions of the disperse phase (isomorphous substitution, e.g., in the case of inorganic auxiliary agents by replacement of Mg^{2+} by Al^{3+}).

In weakly polar dispersion media, only the first three mechanisms are important.

An electrical double layer then tends to form around the particles because they attempt to capture oppositely charged ions from the solution to reestablish electrical neutrality. Brownian molecular motion, on the other hand, tends to distribute the oppositely charged ions uniformly in the external phase. The two opposite effects result in the formation of a diffuse double layer whose characteristic thickness l_D can be determined from the Debye–Hückel theory [21], [33] and by the Poisson–Boltzmann equation. This indicates that the extent of the layer must increase with the absolute temperature T and the dielectric constant ε of the dispersion medium. It decreases as the electrolyte concentration n increases since the particles shield each other over paths of decreasing length, and it decreases as the charge q of the electrolyte's ions increases. The results is that

$$l_D = \sqrt{\frac{\varepsilon k T}{2e^2 n z^2}} \tag{4}$$

where k is the Boltzmann constant, e is the elementary charge, and z is the valence of a symmetrical electrolyte. At large distances from the particle surface, the effective charge approaches zero. This obviously means that particles that are widely separated have no effect on each other. Repulsive forces only come into operation if the particles are so near that their ion clouds are in contact.

The electrostatic interaction of dispersed particles can be assessed quantitatively if the potential gradient in the diffuse electrical double layer is known. For the energy of interaction V_w of spherical particles of equal size having radii a, which should be large compared with $1/x$, and having low, equal interfacial potentials ψ_0, the following approximation is valid [21]:

$$V_w = (1/2)\,\varepsilon a Y_0^2 \cdot \ln\left[1 - \exp\left(-x \cdot d\right)\right] \tag{5}$$

where d is the shortest distance between the particles. It is impossible to determine ψ_0 experimentally since moving particles entrain films of liquid, but the zeta potential ζ is measured in the shear surface of the diffuse double layer of the particles; this is not identical to the interfacial potential, but both quantities are virtually identical in weakly polar phases.

For methods of measuring ζ, see also [9, p. 216], [32].

3.2.2. Steric Stabilization

Steric stabilization of colloidal dispersions by means of natural polymers has been in use for ca. 5000 years, when instant inks for papyrus were prepared in Egypt by mixing lamp-black with a solution of a natural steric stabilizer (e.g., casein from milk, egg albumin, or gum arabic). The suspension was then poured into mold and dried. When required for use, it was simply dipped in water and the sterically stabilized soot particles redispersed spontaneously.

Steric stabilization is used in many industrial products, such as paints, glues, inks, pharmaceutical and foodstuff emulsions, latices, or dispersions of magnetic pigments for manufacturing magnetic tapes.

Steric stabilization has several advantages over other methods of stabilization: (1) it is relatively insensitive to high electrolyte concentrations; (2) the dispersions can be redispersed; (3) dispersions with a high solids content have relatively low viscosities; and (4) steric stabilization is equally effective in aqueous and nonaqueous systems. Sterically stabilized dispersions also exhibit good stability with respect to freezing and thawing.

In contrast to electrostatic repulsion, steric repulsion does not have a long range, but repulsion increases asymptotically at small distances. This latter situation is also described as hard interaction, as distinct from (soft) electrostatic interaction. Since steric repulsion is stronger than van der Waals interaction, sterically stabilized dispersions such as, e.g., latices in dispersion media that are good solvents for the stabilizer, can be thermodynamically stable; therefore, they do not fit into the lyophobic–lyophilic colloids scheme.

Stabilizers. Steric stabilization is caused by macromolecules or by surfactant molecules which are (1) absorbed, (2) grafted on, or (3) form part of the particle.

The best stabilization for colloidal dispersions is produced by macromolecules that form part of the particle, are anchored to it by a chemical bond, or are grafted onto it. Modifications of this type have been carried out with clays, bentonites, and SiO_2 particles [34]. With adsorbed polymer stabilizers, a distinction must be made between the homopolymers and block or graft copolymers.

For adsorption to occur, the interaction between the polymer and the particle must be strong (hydrogen bond formation, dipole forces, or dispersion forces) and that between the polymer and the solvent weak; otherwise, the shear stress produced in a collision would cause lateral movement or even desorption of the stabilizer. On the other hand, for steric stabilization the interaction between the polymer and the solvent must be good. Therefore, steric stabilization is not easily achieved with homopolymers. However, the problem can be solved by using block and graft copolymers in which insoluble anchoring segments are combined with soluble stabilizing units. Simple examples of effective steric stabilizers for aqueous systems are poly(vinyl alcohol – vinylacetate) graft polymers or poly-(styrene – oxyethylene) block polymers and, for nonaqueous systems, poly(acrylonitrile –styrene) block polymers and poly(vinyl chloride – isobutene) graft polymers.

Most polymers are present in solution as a random coil, which is adsorbed at the interface, where in some cases it remains unchanged (Fig. 2 A), but in others it spreads out (Fig. 2 B). If the coils spread out tails (a), loops (b), and trains (c) may be produced at the interface.

Figure 2. Models representing the adsorption of tangled molecules on solid surfaces
A) Adsorption as a tangled molecule B) Adsorption as a spread-out macromoleculea) Tail; b) Loop; c) Train

Depending on the concentration and structure of the polymer and the interactions of the systems polymer – substrate, polymer – solvent, polymer – polymer, and solvent – substrate, very different configurations may be produced and the layer thicknesses may vary considerably, Graft polymers with good anchoring structures may attach themselves so that the main chain forms the train and the grafted side chains form the tails (Fig. 3).

Figure 3. Configuration of graft polymers at a solid surface

With block polymers, it is believed that almost any relationship between loops and tails may be established, depending on the arrangement of the anchoring blocks.

The thickness of the polymer layer (10 – 100 nm) can be determined from the hydrodynamic radius of the particle by viscosity measurements, electrophoresis, and dynamic light scattering [35] or by means of neutron scattering experiments [36]. The interactions of

polymer layers on mica have been measured [37].

Stabilization Mechanisms [22]. The principles of steric stabilization are now well understood, an essential distinction being made between entropy stabilization and osmotic stabilization.

Entropy Stabilization (volume restriction). When two particles approach each other, overlapping takes place between the adsorption layers consisting of surfactants or polymers, which restricts the number of possible configurations (Fig. 4).

Figure 4. Volume restriction

MACKOR first calculated the loss of configurational entropy for a small rigid rod attached to a platelike particle, otherwise free to move, as a result of the approach of a second platelet [38]. This theory was later extended to spherical particles and to neighboring molecules, that obstruct each other [39]. Other theories take account of the flexibility of the chains [22]. However, because entropy stabilization could not explain the coagulation of a dispersion with rising temperature, a second stabilization mechanism had to be looked for.

Osmotic (Enthalpic) Stabilization. When two particles approach each other, solvent is displaced from the region of macromolecular overlap (Fig. 5). As a result, the concentration of the macromolecules in the region of overlap increases and osmotic forces are produced, pulling the solvent back into this region and, thus, producing a separation of the particles [40]. The osmotic stabilization is greatly influenced by temperature and solvent. This explains the dependence of steric stabilization on the solvent and the flocculation of a sterically stabilized dispersion at the Θ-point, the temperature at which interaction between macromolecules and solvent is just as high as that between the segments of the macromolecules.

Figure 5. Schematic illustration of osmotic stabilization

Temperature Dependence of Steric Stabilization. Depending on whether stabilization is entropic or enthalpic, destabilization may occur on cooling or heating (Table 3). Stabilization in aqueous media is predominantly enthalpic, and in nonaqueous media it is predominantly entropic [41]. The effect of temperature is more pronounced for steric stabilization than for electrostatic stabilization, and a sharp transition occurs from long-term stability to flocculation, which is generally reversible, at the critical flocculation temperature (CFT). This temperature may be affected by the presence of an electrolyte.

Further Polymer Effects. Steric stabilization becomes more effective as the molecular mass increases. Complete coverage of the particle surface is required. If this latter condition is not fulfilled, the dispersion is destabilized. In addition, free polymers can also affect the stability of dispersions.

Bridging Flocculation. If the dispersed particles are only partially covered with polymers and the macromolecules of the latter have a sufficiently high molecular mass, they may anchor themselves to two particles at the same time, thus forming polymer bridges and causing flocculation to occur. This phenomenon is termed bridging flocculation [43], [44] and is of great importance in clarifying wastewaters, processing minerals, precipitating sols, and dewatering sludges. These applications require a few mg/kg of a high molecular mass polymer (molecular

Table 3. Thermal stability of sterically stabilized emulsions [42]

Water-in-oil	PLM	PAA	water	1-pentanol	cooling	entropic	301 ± 3
Water-in-oil	PS	PEO	water	cyclohexane	cooling	entropic	308 ± 3

[a] PEO = poly(ethylene oxide); PVA = poly(vinyl alcohol); PAM = polyacrylamide; PAA = poly(acrylic acid); PLM = poly(lauryl methacrylate); PS = polystyrene; PVAc = poly(vinyl acetate);
[b] CFT = critical flocculation temperature

mass at least 10^6) such as polyacrylamide. The polymers may be nonionic, anionic, or cationic. It should be noted that ionic polymers of even relatively low molecular mass (ca. 10^4) may initiate flocculation, but in this case the surface charge density is reduced by charge neutralization.

Sensitization. The way polymer solutions are mixed with dispersions determines the result decisively because of kinetic irreversibility of the adsorption. Dispersions, in which particles are unevenly covered with polymers, will become more sensitive to the effect of electrolytes than those containing particles with no polymer layer on them; see, for example, [43], [45].

Depletion Flocculation and Depletion Stabilization. The question of depletion flocculation and depletion stabilization with high polymer concentration and high solids content has been under discussion for several years [46]. Both effects are initiated by freely dissolved nonionic polymers.

Figure 6 shows a plot of free energy versus distance for spheres in aqueous solutions of poly-(ethylene oxide) for different polymer concentrations. If the maximum is higher than 15 – 20 kT, *depletion stabilization* occurs (a). If the maximum is between 5 kT and 15 kT, *depletion flocculation* results (b), and if the maximum is smaller than 5 kT, no effect can be observed (c).

Thus, at relatively low concentrations flocculation occurs (even in sterically stabilized dispersions), whereas a high concentration results in stabilization.

When two particles approach each other, the concentration of free polymer between them is decreased. In a good solvent this is energetically unfavorable, and the energy of the system increases. If the particles come still closer together, the polymer is almost completely displaced from the volume between them, which consequently is filled with almost pure solvent. At this point a closer approach is energetically favorable since it results in mixing of almost pure solvent with polymer solution, and the result is depletion flocculation. If it is not possible to displace the polymer from the volume between the particles, depletion stabilization occurs.

Figure 6. Energy diagram for two spheres (radius 77.5 nm) for aqueous solutions of poly(ethylene oxide) (M_r 20 000) at polymer volume fractions of a) 0.07; b) 0.04; and c) 0.02

Depletion stabilization differs from steric stabilization in two respects: (1) the stabilizing polymer can move freely in the solution and is not adsorbed on the particle and (2) stabilization due to free polymers is kinetic (and thermodynamically metastable) whereas stabilization due to adsorbed polymers is thermodynamic.

Figure 7. Variation in potential between two particles according to the DLVO theory [19], [21], [50] at various electrostatic potentials

a) $l_D \to \infty$; b) l_D 100 nm; c) l_D 33.3 nm; d) l_D 10 nm; e) l_D 3.3 nm; f) l_D 1 nm

3.3. DLVO Theory

Precise knowledge of the potential as a function of the distance between two particles in a dispersion medium would be an excellent aid in assessing a dispersion. Initially, the variation in potential was determined for model dispersions of spherical particles with a narrow size distribution [5], [36], [47] and for dispersions of platelike particles [48] by measuring the osmotic pressure [5], [48]. Dynamic light scattering [47] and neutron scattering experiments [48], [36] were also carried out. For the purpose of calculation, the teams of Verwey and Overbeek [21] and Derjaguin and Landau [49] (DLVO) independently superimposed the interaction of the energy of attraction E_{attr} and repulsion E_{rep} on each other. The resultant energy of interaction E between two highly charged, spherical, dispersed particles is then given by

$$E = E_{\mathrm{rep}} + E_{\mathrm{attr}} \tag{7}$$

Figure 7 shows the resultant interaction potential E versus the reduced distance d/a of the particles. The particle radius a is 100 nm and the Hamaker constant A has a value of 10^{-19} J. The electrostatic potential ψ_0 varies. For $\psi_0 = 12.8$ mV, a decreasing potential results in an unimpeded coalescence, whereas doubling ψ_0 to 25.6 mV ensures complete stability.

If two particles approach each other at an electrostatic potential of $\psi_0 = 19.2$ mV, the approach is initially favored by a weak minimum. Agglomeration results if the thermal energy of the particles is insufficient to overcome this minimum. The stability of the agglomerates depends

on the depth of the minimum. If the droplets overcome the minimum as a result of their thermal energy, they are again able to move freely in the external phase. Coalescence is initially prevented during further approach because work must be performed in order to overcome the rise in the potential energy.

To prevent the minimum which results in agglomeration, the electrostatic repulsion potential must be increased.

In Figure 8 the electrostatic shielding length, l_D (Debye length) is varied at a constant electrostatic potential of 25.6 mV and a Hamaker constant A of 10^{-19} J. If the Debye length is increased > 10 nm, the stability of a dispersion constantly increases. However, if the Debye length is reduced, the electrostatic repulsion potential becomes virtually insignificant, just like case (e) in Figure 8 [19], [21], [50].

In its original form, DLVO theory applies to highly charged boundary layers with no account taken for steric factors. Expanded model calculations are now available for weakly charged and uncharged boundary layers [51]. To assess the stabilizing action of polymeric substances, the Flory–Huggins parameter was included in DLVO theory. Usable results are claimed if the polymers that are used have no appreciable interfacial properties [52].

4. Destruction of Disperse Systems

4.1. Forces and Mechanisms

To destroy a disperse system, the forces that stabilize a dispersion must be weakened or eliminated while the attraction forces and bonding mechanisms operating between the dispersed particles must be strengthened.

As a result of Brownian molecular motion and van der Waals forces, the dispersed particles approach each other so closely that a combination may take place (cf. Section 3.1). Figure 9 shows the bonding mechanisms that may operate in such a combination. Coalescence of the particles may take place with (A) or without (B) the formation of a material bridge.

When a *material bridge* is formed between two particles, intergrowth may be caused by crystallization effects, but the particles may also combine by fusion or sintering. This produces aggregates that can no longer be dispersed. *Liquid bridges* (b) also enable particles to combine. Substances may crystallize inside the liquid bridge, which causes the particles to fuse together, and if this occurs, redispersion is no longer possible. Liquid bridges may be formed by highly viscous liquids or by capillary forces; it depends on the forces inside the bridge whether indestructible aggregates are formed or whether agglomerates that can be redispersed by supplying sufficiently high mechanical energy are formed.

Figure 9. Bonding mechanisms between particles with the formation of a material bridge (A) and without the formation of a material bridge (B)
a) Intergrowth; b) Liquid bridges; c) Steric bridges; d) Coalescence; e) Electrical forces

Steric bridges (c) are formed when polymers are used and when the interfaces are incompletely covered (bridging flocculation,see page 7); these bridges generally result in the formation of aggregates that flocculate.

Without the formation of a material bridge, two particles coalesce if the liquid layer between them is ruptured when they approach each other, and coalescence (d) takes place if van der Waals attraction forces considerably exceed the repulsion forces. Coalescence leads to aggregation, and redispersing is then no longer possible. Oppositely charged particles also combine without a material bridge being formed (e), and the addition of oppositely charged substances is a method used to destroy a disperse system. Thus, a dispersion that has been stabilized, for example, by an anionic surfactant is broken by adding

a cationic surfactant. As a rule, a sparingly soluble complex is produced which precipitates from the solution.

4.2. Practical Methods

To destroy a dispersion, the mechanisms that counteract agglomeration or aggregation must be eliminated. In addition, the molecules absorbed on the particle surfaces must be removed. Following is a list of the possible methods to destroy a dispersion:

1) *High temperature* increases the thermal energy, which overcomes the repulsive forces. Elevated temperature may also change the adsorption conditions, producing, for example, melting of the dispersant, increased crystal growth, or a change in the crystal form.
2) *Electrolyte addition* reduces the electrical double layer and the electrostatic repulsion potential. Electrolytes may also have a dehydrating action.
3) *Electric fields* result in the particles being discharged.
4) *Desorption of dispersant particles* can be achieved by precipitating them or by displacing or detaching them from the particle surface. The dispersants can be precipitated by using flocculating agents or by decreasing the solubility of the dispersant either by adding a salt or by changing the pH. The addition of a less effective dispersant may displace the more effective one. The adsorption of the dispersant by competing adsorption to another substance also leads to dispersant detachment.
5) *Mechanical loads,* particularly a *shearing load,* may destroy a dispersion.
6) *Freezing* may destroy the dispersion.

5. Dispersants

Definitions. *Dispersants* are products or mixtures of products that can promote the formation of a dispersion or stabilize a dispersion. The term *dispersion* is applied to a system of several phases in which one is continuous and at least one other is finely distributed [53]. The preparation of a dispersion is called *dispersal.*

A dispersant generally does not change the solubility of the substance to be dispersed. In contrast, *hydrotropic substances* increase the solubility of a substance that is sparingly soluble in water; the more general term is a *lyotropic substance* [54]. Whenever the additive is a surfactant, the term *solubilization* is used [55]. *Sequestration* occurs when sparingly soluble salts are solubilized by chelating their cations [54]. In practice, no sharp division exists between dispersants (no solubilization) and lyotropic substances (significant solubilization). In general usage, the term *dispersant* is used for a product that can disperse sparingly soluble solids in liquid phases and keep them finely dispersed [56]. In the strict sense, it is more precise to use the term *suspending agent* whenever a solid is finely dispersed in a liquid (→ Emulsions).

The term *flocculation protection* describes a dispersant used to prevent a solution from turning into a colloidal dispersion or becoming turbid [54], [58]. The re-formation of a stable dispersion from flocks or aggregates is called *peptization* or *deflocculation* [54].

In a dispersion of solid particles, such primary particles as agglomerates and aggregates may be encountered. *Agglomerates* are combinations of coalesced particles that can be redispersed. In contrast, *aggregates* can no longer be dispersed because the particles have, for example, undergone intergrowth [57].

5.1. Dispersant Classes

Dispersants are generally polyelectrolytes that are readily soluble in water. The most common representatives are alkali-metal polycarbonates, polysulfonates, or polyphosphates, usually sodium salts. The use of ligninsulfonates and of condensation products of aromatic sulfonic acid with formaldehyde is very widespread.

At present, polyphosphates are still used in the detergent industry, e.g., for colloidally dispersing dirt detached from the fibers and for sequestering calcium and magnesium ions in the detergent liquor. In low-phosphate detergents, polyphosphates are completely or partially replaced by zeolites (→ Laundry Detergents) [59]. Polycarbonates have also been proposed for this purpose [60]. The structural details of common

dispersants have not yet been fully elucidated; therefore, only schematic structures are given in the following for the various dispersants. In the case of formaldehyde reaction products, the degree of condensation is not known since. When two to ten aromatic nuclei are linked together, there is no reliable method known for determining the molecular mass.

5.1.1. Ligninsulfonic Acids

ligninsulfonic acids [*8062-15-5*] are made from native lignin [*9005-53-2*]. Two different starting materials are available: (1) lignin made from sulfite pulping and (2) lignin made from alkaline (kraft) pulping of wood (→ Lignin). In the first case, the sulfite waste liquor is purified and marketed as a liquid or a solid. Lignin from kraft pulping is first purified and then sulfonated.

Industrial ligninsulfonates are globular colloids with molecular masses between 2000 and 100 000 whose structures have not yet been fully elucidated. Their basic structural unit is phenylpropane. The structural formula shows five structural units linked with the parent unit in various ways (Fig. 10) [61]. The degree of sulfonation varies between 0.3 and 1.0 sulfite groups per phenylpropane unit [57].

Figure 10. Partial structure of ligninsulfonate

The suitability of ligninsulfonates for various industrial purposes depends on the purity, degree of sulfonation, number of hydroxyl groups, and molecular mass distribution of the sulfonates. In addition to highly dispersive action during milling and ease of redispersion, ligninsulfonates must be easily soluble and the dispersions stable at higher temperature. These properties are achieved by suitable purification and chemical treatment of the crude product (→ Lignin).

Ultrafiltration of the sulfite waste liquor can be used to separate the ligninsulfonates into high molecular mass and low molecular mass fractions. Products with a low degree of sulfonation and an increased hydroxyl and carboxyl content are produced by *alkaline and oxidative treatment* [62]. Dispersants for pigments and dyes can also be prepared by *thermal degradation* of ligninsulfonic acid [63].

Ligninsulfonates with a relatively high degree of sulfonation are very effective milling additives. On the other hand, products with fewer sulfonic acid groups are more thermally stable; these products adhere more strongly to the hydrophobic surfaces of the dye particles than highly sulfonated products and are not as readily separated by Brownian thermal movement [64]. Therefore, thermally stable dispersions are obtained by using dispersants made from kraft lignin with few sulfonic acid groups [65] (→ Lignin). Leveling agents for dyes have long been prepared by reacting the ligninsulfonates with various monofunctional (aniline or chloroalkanes) or bifunctional (ethylene oxide or aliphatic diamines) compounds [66]. Similar reaction products have been proposed as dispersants for paint manufacture and dyeing [67]. For example, Schutzkolloid 63-Bayer (protective colloid 63) is made by reacting ligninsulfonic acid with aniline.

Disadvantages of ligninsulfonates are their reductive effect on sensitive azo dyes in high-temperature dyeing (130 °C) and their tendency to soil fibers, which with polyamide and wool may lead to a yellow discoloration of the fibers when exposed to light. The foaming ability of these products may also occasionally cause problems. Improved ligninsulfonates have been developed [68].

Commercial product names for ligninsulfonates and their derivatives are as follows [69]: Dekol N, CN (BASF); Lamepon N (Grünau); Lignosol (Lignosol, Canada); Lyocol A powder (Sandoz); Reax brands (Westvaco); Sulfite waste liquor, Waldhof liquor, Zewa powder (Zellstoff Waldhof); Schutzkolloid 63 (Bayer); Ufoxanes, Ultrazines (Messrs. Borregards, Norway); Unisol N powder (PUC-FMC); Irgasol AT (Ciba-Geigy).

5.1.2. Formaldehyde Condensation Products

Table 4 summarizes important dispersants produced by condensation of aromatic compounds with formaldehyde. The following describes a typical production of a dispersant of this category. With suitable variations it can be applied to a number of products formed by condensation with formaldehyde [*50-00-0*]. [70], [71], [72], [73], [74], [75], [76], [77], [78], [79]

Naphthalene (200 parts) is reacted with 200 parts of 98 % sulfuric acid for 5 h at 160 – 165 °C in an iron tank. After the solution has been cooled to 80 °C, the mixture is diluted with 90 parts of water in a lead-lined stirring vessel. Then 107 parts of a 30 % formaldehyde solution are added and the mixture is stirred for 20 h at ca. 80 °C. Toward the end of this period, the mixture is gradually heated to 100 °C. Neutralization is carried out at 20 – 25 °C with ca. 165 – 180 parts of a 25 % ammonia solution. The neutralization product is then filtered and, if necessary, dried in a vacuum drum drier [80].

Numerous variations of this synthesis are possible, and a wide range of aromatic compounds and their derivatives can react with aldehydes, ketones, and compounds that eliminate aldehyde groups. The following three typical examples supplement those listed in Table 4:

1) Dispersants produced by condensation of aromatic sulfonic acids and benzyl chloride [*100-44-7*] or benzoin [*119-53-9*] [81]
2) Dispersants produced by condensation of various alkylarylsulfonic acids with a halogen arylsulfonic acid [82]
3) Dispersants produced by condensation of sulfonated phenols, 2-naphthols, etc. with formaldehyde and various nitrogen compounds [83]

Finally, special processes have been developed for improving the quality of dispersants or for adapting them to special applications [57]. Thus, the following specific products can be prepared:

Products with low sulfate content [84]
Low-foam, alkali-resistant sulfomethylation products obtained from mono- and polynuclear phenols [85]
Thermostable condensation products [86]
Low-foam condensation products obtained from diphenyl derivatives [73]
Ethoxylated and sulfated condensation products obtained from alkylphenols and formaldehyde [87]
Thermostable sulfomethylation products [88]
Phenol – formaldehyde condensation products containing sulfonic groups and having improved dispersive action [89]
Products that have no reducing action on sensitive dyes
Almost colorless sulfomethylation products that are also suitable for optical brighteners [85], [90]
Dispersants that do not stain fibers [87], [91]
Postcondensed products with improved dispersive properties [92]
Phenol – formaldehyde – hydrogen sulfite condensation products that contain nitrogen and are low in alkali concentration

Commercial polysulfonate products are listed as follows [69].
Condensed sulfonates: Avolan IS (Bayer); CHT dispersants SMS (CHT); Dispersant EB (PUC-FMC); Dupramin DS (AKZO); Dyapanol (Yorkshire); Irgasol DAM (Ciba-Geigy); Lyocol O, Lyocol RD, Lyogen PN (Sandoz); Matexil DA-AC (ICI); Osimol DPA (Grünau); Setamol WS (BASF); Solegal A, P (Hoechst).
Liquids: Tamol NH, NNO, NOP (BASF); Tanede DPA (Tanatex); Texamol WS (ACNA); Vultamol (BASF); Wotamol WS (VEB Wolfen); Baykanol PQ, Baykanol LS, Dispersant SS, Dispersant 523 (Bayer); Melmeny (SKW Trostberg), Lissatan AC (ICI); Demol N (Bayer, Japan).

These important dispersants find applications in the following fields [93]:

1) Milling additives and dispersants for pigments and dyes
2) Dispersants and plasticizers in the building industry
3) Dispersants for polishing and abrasive powders
4) Stabilizing agents for resin glue emulsions, e.g., Tamol NOP (BASF)
5) Auxiliary agents in the emulsion polymerization of synthetic rubber
6) Dispersants for fillers, pigments, and vulcanizing agents in natural and synthetic rubber latices

Table 4. Aromatic formaldehyde condensation products

Production	Structural unit	References
Naphthalene [*91-20-3*] + H_2SO_4 + formaldehyde		[70]
Naphthalene [*91-20-3*] + cresol [*1319-77-3*] + H_2SO_4 + formaldehyde		[71], [72]
Diphenyl ether [*101-84-8*] + H_2SO_4 + formaldehyde		[73]
Toluene [*108-88-3*] + H_2SO_4 + formaldehyde		[74]
Isopropylbenzene [*98-82-8*] + H_2SO_4 + formaldehyde		[75]
Cresol [*1319-77-3*] + H_2SO_4 + formaldehyde		[76]
Phenol [*108-95-2*] + formaldehyde + sodium sulfite		
Cyclohexanone [*108-94-1*] + formaldehyde + sodium sulfite		[77]
Maleic anhydride [*108-31-6*] + formaldehyde + sodium sulfite (melamin)		
Phenol [*108-95-2*] + H_2SO_4 + formaldehyde		[78]
Aliphatic ketones + formaldehyde + sodium hydrogen sulfite		[79]

7) Boiling-temperature degreasing agents to which Tamol N brands (BASF) have been added to improve the stability of the solution and increase its dirt-suspending power

5.1.3. Protein Condensation Products [69, p. 523]

Protein-derived dispersants are obtained, for example, by condensation of natural protein hydrolyzates from collagen with fatty acids or abietic acid; the products are marketed as potassium or triethanolamine salts [94]. Examples of commercial products are as follows:

$C_{11}H_{23}CONHCHRCO-(NHCHRCO)_n-NHCHRCOOK$
Lamepon S (Grünau)
$C_{11}H_{19}CO-(NHCHRCO)_n-NHCHRCOOK$
Lamepon UD (Grünau)
$C_{19}H_{29}CONHCHRCO-(NHCHRCO)_2-NHCHRCOOH \cdot N(CH_2CH_2OH)_3$
Lamepon PA-TR (Grünau)

Slightly degraded polypeptides are as follows: Lamasan CL (Sandoz); Ofnapon AS, Ofnapon ASN (Hoechst); Protepon (Protex).

5.1.4. Polymers [69]

Water-soluble polymers are used both in the production of dispersions and in the preparation of dye dispersions and in the preparation of polymer dispersions. Examples of suitable compounds are

poly(vinyl alcohol) [*9002-89-5*]
poly(vinyl pyrrolidone) [*9003-39-8*]
poly(vinyl sulfates)
polyacrylates
polyacrylamide [*9003-05-8*] [95]
maleic acid–styrene copolymers

Polymeric compounds often have a synergistic effect in disperse systems. Even small additions may decisively improve the quality of dye dispersions [96]. The polymers probably form complexes with the dispersants, and these complexes have a solubilizing effect on certain dyes. Such complexes have been found in mixtures of poly(vinyl pyrrolidone) and sodium alkylsulfates [97]. Alternatively, the quality-improving effect of polymers on dye dispersions may be caused by complex formation between the polymer and the dye, because poly(vinyl pyrrolidone) and alkyl or alkylphenol polyglycol ether have been found to form complexes with suitable dyes.

A further field of application of polymeric dispersants is the plastic industry. Many polymers are produced as dispersions (latices), and these have found varied and widespread fields of application, often by adding further emulsifiers or dispersants [112].

A distinction is made between self-dispersable polymers such as, for example, polyurethanes, which have ionic and nonionic water-soluble groups, and those polymers in which dispersability must be achieved by adding dispersants [9].

5.1.5. Surfactants

Surfactants [98] are not usually considered as dispersants although they often have dispersive properties. Their use is of decisive importance, for example, in the conditioning of pigments that are sparingly soluble in water or in the further processing of such pigments in polymer dispersions. The wetting properties of the surfactants are particularly important when pigments are mixed with polymer dispersions. In this case, the surfactants must be compatible with the dispersions and cationic surfactants are usually ruled out, because they form insoluble complexes with the anionic dispersants which than destroy the dispersions.

The following anionic or nonionic surfactant classes are particularly suitable: alkylpolyethoxylates, e.g., Ekalin F (Sandoz); alkylphenol polyethoxylates, e.g., Alkol SMK (Sandoz); alkylamine polyethoxylates; carboxymethylated alkylphenol polyethoxylates, e.g., Lyocol AC (Sandoz); polyalkylene oxide compounds and their sulfuric acid or phosphonic acid esters; alkylsulfonates or alkylsulfates; alkylarylsulfonates; sulfated fats or oils, e.g., Lyogen P (Sandoz); salts of fatty or resin acids; reaction products of diamines or triamines with ethylene oxide, e.g., Sandogen NH (Sandoz) [99]; weakly anionic, amphoteric fatty acid amides containing sulfonic groups, e.g., Tergolix A (Sandoz).

In addition to the products already mentioned, mixtures of nonionogenic and anionic dispersants that are supplemented with noninterfering foam-suppressing agents are also commercially available. Examples are Lyocol WPN (weakly anionic) and Lyocol ACN (anionic), both made by Sandoz.

5.1.6. Polyphosphates and Derivatives

Polyphosphates, particularly pentasodium triphosphate [*7758-29-4*], $Na_5P_3O_{10}$, M_r 367.93, have been long used in detergents for dispersing dirt detached from the fibers and sparingly soluble calcium and magnesium soaps in the wash liquor. The use of these dispersants prevents graying of the laundry and improves the degree of whiteness. However, because of the eutrophication problem, detergent manufacturers have begun to replace the polyphosphates with other complexing agents (→ Laundry Detergents).

5.1.7. Other Dispersants

Some dispersants are difficult to classify. Examples are disproportionated abietic acid (Dresinat; Hercules) [70, p. 408] and starch derivatives [80, p. 2769].

5.2. Properties and Mode of Action

Surface Tension. All dispersants that are readily soluble in water do not lower the surface tension γ of water as much as surfactants. Table 5 shows the surface tension of solutions containing 5 g/L of dispersant. As a comparison, the surface tension of a surfactant (dodecyl alcohol heptaglycol ether, DA-7) [55] is quoted for the same concentration and temperature.

Time-dependent measurement shows that the surface tension of dispersants varies with time in a characteristic way (Fig. 11) [101]. This phenomenon is explained by the presence of several compounds, e.g., in Dispersant SS; these compounds diffuse to the surface of their solution at different rates and will be adsorbed there one after another.

Table 5. Surface tension of dispersant solutions *

Dispersant	Surface tension, mN/m
Waldhof liquor	52.7
Schutzkolloid 63	64.7
Baykanol PQ	71.5
Baykanol SL	54.6
Dispersant 523	48.0
Dispersant SS	61.6
Avolan IS	68.3
Melment	71.3
Demol N	71.9
DA-7	31.6

* Surface tension measured by the ring method [100] after leaving the solution for 1 h at 20 °C

Figure 11. Surface tension of a solution of an anionic dispersant * (1 g/L) as a function of time at 20 °C
* Dispersant SS, made by condensation of cresol, naphthalenesulfonic acid, and formaldehyde

Dispersive Action. The main effect of dispersants is their ability to disperse finely ground solids in aqueous media and to stabilize the dispersion. Although certain models of dispersive action have been developed, these models fail to satisfactorily explain the action of a dispersant [98], [69]. As a phase is further dispersed within another phase, the interface area between the two phases increases. Therefore, the properties of the interface determine the behavior of a disperse system [102], and the action of the dispersant molecules at the solid particle interface acquires special significance. Figure 12 summarizes diagrammatically the possibilities encountered [103]. For monomeric and polymeric molecules, the attractive and repulsive forces and their interaction are treated in more detail in Chapter 3.

Dispersants have several hydrophilic groups along their chain and a comblike structure. In contrast, surfactants have one polar hydrophilic group and a long hydrophobic chain. Therefore

surfactants are alignes with their long axes perpendicular to the particle surface, whereas the absorbed polyelectrolyte molecules are parallel to the particle surface with the polar groups directed outward [104]. The particles of the substance to be dispersed are generally negatively charged; therefore, they push the negatively charged groups of the polyelectrolytes away toward the solution. The recombination of particles by agglomeration or aggregation is counteracted by the following mechanisms:

1) *Electrical repulsion* of the negative groups directed toward the solution. The stability of dispersions depends very strongly on electrolyte additives and the thickness of the electric double layer decreases as the ion concentration increases. Therefore, the stability of the dispersion decreases both as the electrolyte concentration increases and as the valence of the counterions increases (Shultze–Hardy rule). According to calculations, monodisperse systems are more stable than dispersions of compounds with varying radii and surface potentials [69], [105].
2) *Steric action* of the hydrated ionic groups. Dispersants are readily soluble in water, which suggests that their numerous ionic groups have extensive hydrate envelopes. These hydrated groups act as barriers when the particles approach distances at which the attraction due to van der Waals–London forces could become effective.
3) *Structural change of the aqueous phase* by the saltlike nature of dispersants. Figure 13 shows that small additions of a dispersant may raise the cloud point [106] of a polyglycol ether solution significantly. Raising the cloud point is approximately equivalent to increasing the rigidity of the water structure, and this counteracts agglomeration or aggregation.

The action of a solubilizing substance differs from that of a dispersant. Solubilizing surfactants form micellae that can include the sparingly soluble compound in their interior hydrophobic parts [55]. Surfactants have limited solubility in water, whereas dispersants always have a good, often very high, solubility in water.

Figure 12. Stabilization of a dispersion

Destruction of Dispersions. The mechanisms and methods that lead to the destruction of a dispersion are treated in Chapter 4.

5.3. Applications

Since the fine dispersion of sparingly soluble solids in aqueous media is an inexpensive process, which presents few hazards, the application of dispersants is varied and widespread. Large quantities of dispersants are used in the following fields:

Conditioning of dyes or pigments
Disperse dyes and dispersants for the textile industry
Production of polymer dispersions

Detergents
Photographic industry
Agriculture
Cosmetic and pharmaceutical industries
Cleaning and polishing products

5.3.1. Conditioning of Dyes or Pigments
[57], [69], [71]

Sparingly soluble dyes or pigments are used on a large scale in dispersed form. Such dispersions, actually suspensions, of colorants are industrially important, especially as pigments in binders and as emulsion paints in water or other media. When applied, pigments continue to form a colloidal two-phase system (pigment in binder), whereas disperse dyes, when used in the suspended form, are converted into a molecularly dispersed state on or in the fiber (→ Disperse Dyes).

Disperse dyes are used chiefly for textile dyeing, but pigments find application in many different industry branches such as car paints, industrial paints, indoor and outdoor paints, printing inks in the graphics industry, coloration of plastics, and textile printing.

The synthesis of sparingly soluble dyes produces coarse crystals (filter cakes), the particle size of which must be reduced in the presence of dispersants before or after drying. Various devices are used for grinding the filter cake, depending on the rheological properties [105]. Normally beater additives (e.g., Tamol N brands; Bayer) are used, which are capable of altering the rheological properties of the filter cake.

During grinding the dispersants penetrate the submicroscopic cracks and crevices in the dye particles, assist in separating the primary particles from each other, and protect the particles against agglomeration. However, the dispersants also ensure optimum viscosity for the grinding process and the stability of the dispersion. If the aqueous dispersions are then dried to form powders, further dispersants are added. In this way, the high degree of dispersion required in the final product can be achieved again when the dye is introduced into the dye bath. However, additives are also included in liquid preparations of pigment dispersions to prevent rapid settling and drying [107].

Dyes with hydrophilic groups are easier to disperse than hydrophobic dyes. The stability of dye dispersions also depends on the tendency of the dyes to crystallize, which is influenced by their purity and solubility. Particle size distribution is also a factor, since monodisperse systems are more stable than polydisperse systems [106]. Finally, the stability depends on the dispersant used.

Consi deration must already be given to all these factors during the manufacture of the dye dispersions. Therefore, the choice of dispersant depends both on manufacturing requirements and on the subsequent application. The dispersants used for dyes and pigments are polyelectrolytes such as sulfite waste liquors and their derivatives or sulfonates of aromatic, cycloaromatic, or aliphatic condensation products. Anionic or nonionic surfactants are also used. In addition to their dispersive properties, surfactants enhance the wettability of dye powders [107].

5.3.2. Disperse Dyes and Dispersants for the Textile Industry

After their conditioning vat dyes or disperse dyes are finely divided, generally aqueous, dispersions, pastes, or powders. All three forms must be readily dispersable in the dye bath and the dispersions that are obtained must be sufficiently stable throughout the entire dyeing process. Moreover, the dispersant must not adversely affect the dyeing behavior of the dyes or the results of dyeing. To disperse the sparingly soluble dyes in the dye bath, concentrated emulsions of liquid carriers or leveling agents are usually employed, and the composition of these is described elsewhere (→ Emulsions).

In addition, paraffin, wax, polyethylene, or silicone dispersions are used in the textile industry as waterproofing agents [108], [109]. Inorganic hydrated oxides and aluminum salts and heavy-metal salts of fatty acids such as zirconium stearate are usually added [108].

To disperse crystalline paraffin, ethoxylated sorbitan fatty acid esters, usually mixtures having various HLB values may be used (HLB = hydrophilic – lipophilic balance; for explanation, see → Emulsions). Mixtures of ethoxylated sorbitanyl oleate (Tween 80; Atlas Chemie) and ethoxylated oleyl alcohol have also been used [110] as well as mixtures of ethoxylated oleyl alcohol with various HLB values [111]. Protein – fatty acid condensates are used as codispersants [94].

Waxes may be dispersed with polyethoxylated oleyl alcohol, and polyethylene may be dispersed with ethoxylated fatty alcohols having an HLB value of 10 – 12 or mixtures of lauryl polyglycol ether (HLB = 9) with partially ethoxylated sorbitan trioleate (Span 85; Atlas Chemie). The silicones used are generally liquids; their emulsification is treated elsewhere (→ Emulsions).

5.3.3. Production of Polymer Dispersions

[56], [112], [70, p. 403]

The manufacture of polymer dispersions has been improved to such an extent that new fields of application have been opened up. Thus, for example, the increased durability of outdoor paints enabled colored paints to be used.

A distinction is made between self-dispersable polymers and those which become finely distributed by adding dispersants. Polyurethanes with ionic or nonionic water-soluble groups can be dispersed without further additives. Common polymers are finely dispersed by adding dispersants and additional surfactants, particularly wetting agents.

The manufacture of polymer dispersions is generally carried out by emulsion polymerization [112, part 1]. In this process, the sparingly soluble monomer is emulsified in water. The actual polymerization is initiated by water-soluble radical initiators and then proceeds in the aqueous phase in the polymer particles enveloped by the emulsifier. The emulsified droplets are only responsible for maintaining the supply of the monomer. The emulsion disintegrates during the polymerization, and a dispersion (suspension) of the polymer is produced. The final product is a "synthetic latex" containing particles that are 10 – 100 times smaller than the emulsified monomer droplets present at the beginning of the reaction. The size of the latex particles varies between 50 nm and 3 μm and can be controlled by the choice and quantity of dispersant and by the way in which it is added.

The advantages of emulsion polymerization over block polymerization or over the use of organic solvents in production and application are as follows:

1) Easy removal of the heat of reaction
2) Achievement of higher molecular masses, which results in better product characteristics such as film formation
3) Lower viscosity of the mixes

4) More convenient workup due to the elimination of solvent recovery and avoiding the hazards associated with the handling of organic solvents

Since the polymer latices that are formed are often used directly as coating compounds, adhesives, or for coating and impregnating paper or textiles, they must be, for example, resistant to storage, frost, and electrolytes. Their film-forming properties must not be adversely affected by the addition of pigments, plasticizers, or thickening agents. The adhesion of the dispersant molecules to the polymer particles contributes to the stability of the dispersion, which depends on the dispersant's degree of hydration and on the polymer type [113].

Cationic products are seldom used, since they may interfere with the common initiator systems or precipitate during subsequent use when anionic surfactants are added.

Although condensation products are also used, they are less widespread than anionic, nonionic, and especially hydrophilic surfactants because of their dark color. Most commonly used are anionic alkyl or arylalkylsulfonates, alkylsulfates or salts of natural fatty acids, and resin acids. These produce a relatively large decrease in surface tension and in the solid – liquid interface tension and an increase in the electrical charge of the negatively charged monomer droplets. Both factors result in finely divided, stable polymer dispersions even when small amounts are added [112, vol. I, p. 64]. Nonionic surfactants such as alkyl or alkylphenyl polyglycol ethers are preferred because their critical micelle concentration is markedly lower than that of anionic surfactants. If mixtures of nonionic and anionic surfactants are used, the low critical micelle concentration can be suitably combined with the negative electrical charges. Therefore, the use of such mixtures is common practice in the plastics industry.

Salts of natural fatty acids or resin acids are preferred for the *emulsion polymerization of butadiene* [*106-99-0*] or for the copolymerization of butadiene with styrene or acrylonitrile, but anionic sulfonates or sulfates are also used.

Abietic acid derivatives, which have become known as Dresinat (Hercules), are commonly used in the manufacture of *polychloroprene* [*9010-98-4*]. The use of alkylphenol polyglycol ethers has also been described [114].

If natural *rubber* is being processed, a protein – fatty acid condensate is added to abietic acid as a codispersant [94].

In the polycondensation of certain *polyurethanes,* small quantities of condensed dispersants or readily water-soluble chlorides are added to abietic acid derivatives.

The polymerization of *cis*-1,4-isoprene in solution or the manufacture of *butyl rubber* [*9010-85-9*] has been carried out in the presence of potassium soaps, alkylbenzene sulfonates, cetylpyridinium chloride, or ethoxylated alcohols or alkylphenols [113].

For the *polymerization of styrene* [*100-42-5*], alkylbenzene sulfonates, sulfated alcohols, often together with nonionic products such as polyglycol ethers and polyglycol esters, are used.

In the emulsion polymerization of *vinyl monomers* such as vinyl chloride [*75-01-4*] or vinyl acetate [*108-05-4*], soaps, alkylsulfonates, and sulfosuccinic acid esters are chiefly employed. Vinyl acetate can also be polymerized in the presence of protein – fatty acid condensates [94]. Stabilization with poly(vinyl alcohol) is common in the dispersion of poly(vinyl acetate).

Sulfated alcohols, condensed amines, and recently perfluoro compounds are used for the emulsion polymerization of *ethylene* [*74-85-1*].

For the emulsion polymerization of *ABS polymers* [*9003-56-9*] (copolymer of acrylonitrile, butadiene, and styrene), hydrolyzed, disproportionated colophonium (Dresinat; Hercules), and sodium oleate and sodium alkylbenzenesulfonate are suitable [115], [116].

Water-soluble monomers such as acrylonitrile [*107-13-1*] are polymerized in water-in-oil emulsions. Soaps, sorbitan fatty acid esters, and poly(vinyl pyridinium) salts are used as emulsifiers. The mechanism of this polymerization differs from the described mechanism in that no new particles are formed during the polymerization [117].

To carry out the polycondensation of polyamides or polyesters in emulsion, a mixture of condensed sulfates with suitable polyglycol ethers may be used. Finally, the polycondensation of phenol – formaldehyde resins in emulsion has been attempted, using hydrolyzed proteins and zinc soaps.

5.3.4. Application of Polymer Dispersions

The processing of polymer dispersions involves the addition of further dispersants or dispersion aids, depending on the dispersion's field of application [9, p. 389]. The main fields of application of such polymer dispersions are paints and lacquers, building chemicals, auxiliary materials for the manufacture of paper and paper coatings, textile coating, and colorants for plastics.

Paints and Lacquers. Painting materials contain essentially two components, pigments and binders. A distinction is made between aqueous and nonaqueous systems.

Nonaqueous Systems. In nonaqueous systems, the natural or synthetic resins or oils are dissolved in an organic solvent such as benzene, xylene, or a suitable ester. Pigments are generally finely distributed in these liquids by using dispersing machines (grinding units) or by adding dispersants, antisettling agents, or leveling agents. The dispersants that are used are substances such as disproportionated abietic acid, sparingly soluble naphthenates, or sulfated fats and oils. Common antisettling agents are, for example, thickeners such as fatty acid ethanolamides. Despite their high viscosity, lacquers have excellent brushability. Finally, silicon oils or oligomeric acrylates are used as leveling agents. Lacquers which provide shiny coatings are generally nonaqueous systems.

Aqueous Systems. In aqueous systems, the natural resins or oils must first be emulsified. As a rule, polymer dispersions produced by emulsion polymerization or emulsion polycondensation must first be stabilized before pigments can be added. Liquid – liquid or solid – liquid systems are encountered, but systems exist in which solid and liquid constitutents are dispersed alongside each other. The dispersants used are polyelectrolytes such as ligninsulfonate or condensed sulfonates. Alkylbenzene sulfonates and disproportionated abietic acid are also used. In addition, nonionic polyglycol ethers of alcohols, alkylphenols, condensed phenols, abietic acid, fatty acids, and fatty acid esters are added. To avoid the disturbing effects of polar additives on polymer dispersions with polar structures, nonionic surfactants are often preferred.

The dispersions of natural resins or oils or the synthetic latices are then supplemented with pigments, again by mechanical dispersion. Pigment dispersants, so-called milling agents, are added; condensed sulfonates such as brands of Vultamol (BASF) are suitable [118]. Salts of polycarboxylic and polyacrylic acids or polyphosphoric acid with a medium chain length, cellulose derivatives, or alkylphenyl polyglycol ether, as well as copolymers of ethylene and propylene oxide, are also used. In the final emulsion paints, the binder and pigment particles are stably dispersed alongside each other in the aqueous phase.

The dispersants in such paints, apart from having stabilizing properties, are intended to improve the adhesion of the polymer and pigment particles to the foundation and to promote film formation. The color intensity and the spreading power of the pigments are generally improved by interface-active additives [119, p. 192].

When polymer dispersions are used on plaster, concrete, masonry, cement, or wood for painting facades, walls, or ceilings, or as roofing felt paints, the dispersants added must primarily have a beneficial effect on the rheological properties of the polymer films produced and keep them stable for a long period. In addition, they must contribute to the shelf life and the electrolyte stability. Since the action of each individual dispersant is specific to certain polymer dispersions, there are no general rules governing their use [112, vol. II, p. 48]. Addition of the emulsifier used in emulsion polymerization is recommended, provided that its nature is known or can be determined. In addition to natural or synthetic dispersants, auxiliary agents such as protective colloids or thickeners are often used.

Special mention should be made of polymer dispersions for metal painting such as corrosion protection painting, roof painting, and to an increasing extent, for priming vehicle bodies. In these paints, the choice of suitable dispersants is critical for the formation of smooth films with good adhesion on such nonabsorbent substrates [112, Vol. II, p. 65]. Aqueous polymer dispersions have not acquired any importance as baking enamels thus far.

Building Chemicals. Polymer dispersions are widely used in building materials. The dispersions, which are chiefly manufactured by

emulsion polymerization, are used in plasters and coatings [112, vol. II, p. 32] and as additives in cement mortars and filling compounds [112, vol. II, p. 80], usually with emulsifiers or dispersants also added.

To enable the use of polymer dispersions as plaster in the building industry, as little water as possible should be present to achieve a high flow resistance, which is beneficial in handling the material, and to avoid the risk of shrinkage cracks forming. Dry fillers and pigments are usually worked directly into the polymer dispersion. To prevent coagulation, dispersants such as ligninsulfonate or condensed aromatic sulfonates are added beforehand.

If polymer dispersions are used as filling compounds primarily for producing jointless built-up floor coverings, filler compatibility is an important application factor. Interface properties such as wettability are, therefore, especially important and can be controlled by adding surfactants. If interface-active copolymers are used, the choice of the hydrophilic – hydrophobic polymer ratio is decisive.

Addition of surfactants is essential to produce jointless floor coverings, for example, with an anhydrite base by using the Anhyplan process (BAVG, Bayer Anhydrit Vertriebsgesellschaft), and for the mechanical application of ceiling or wall plasters or facade stuccos. Rapid mechanical application of the material, for example, by means of a pump, must be possible. However, after the plaster has adhered, it must set relatively rapidly. Alkanesulfonates, alkylbenzene sulfonates, and polyglycol ethers of alcohols or alkylphenols are used for this purpose.

Paper Auxiliaries. When pulp or paper coating pulp are manufactured, polyphosphates, complex phosphates, or polyacrylate salts are suitable for the dispersal of white pigments such as china clay or titanium dioxide in water. On the other hand, in colored pigment dispersions, so-called fine pastes, which are used to stain high-quality paper such as laminate paper, alkylnaphthalene sulfonates are generally used. Additions of alkylsulfonates have proved to be successful when plastic dispersions based, for example, on butadiene – styrene or acrylate polymers are used as binders for pigmented paper plasters.

Additions of alkylsulfonates are suitable if polymer plastic dispersions based, for example, on poly(vinylidene chloride), polyurethane, or silicon oil are used to achieve effects on the paper surface such as water repulsion, greaseproofness, or separating action towards adhesive substances.

Textile Coating. Dispersions are used as flaking or coating agents or as binding agents in the textile industry. Fields of application are, for example, the manufacture of artificial leather or carpet backing [120]. Virtually all the polymers are used, especially poly(vinyl acetate), polyurethanes, or polyvinyl – polyalkylene copolymers.

Coloration of Plastics. For coloring plastics, the pigments are added to the polymer dispersions. The dispersants used in the polymer dispersions must be compatible with the pigment dispersants.

5.3.5. Adhesive Dispersions

Dispersions of numerous polymers are used as emulsion-based adhesives. Their oil-in-water emulsions (dispersions) or mixtures of finely divided substances and liquids are also used in various industrial applications.

For bonding wooden furniture parts together, poly(vinyl acetate) or polyamide dispersions are generally used. The packaging industry prefers dispersions of poly(vinyl acetate) or polyacrylate or their copolymers and polychloroprene or polyurethane emulsions as paper adhesives. In the building trade, dispersions of poly-(vinyl acetate), polyacrylate, or polychloroprene and dispersed copolymers of styrene and acrylate are used, e.g., for bonding tiles. The leather industry makes use of emulsion/dispersion-based adhesives that contain polyurethanes, polychloroprene, or vinyl copolymers. Dispersions of polyvinyl – polyalkylene copolymers are required by the textile industry for laminating.

The dispersants used generally lower the interface tension between paper, wood, or other materials and the adhesive used. Since organic solvents themselves have a low surface tension, surfactants are normally only added to aqueous glues to reduce the high surface tension of water.

The governing rule for rubber adhesives is that anionic surfactants are used for anionic

latices, and cationic surfactants are used for cationic latices. To prevent errors, nonionic surfactants are generally used. Alkylsulfonates, alkyl ether sulfates, or ethylene oxide – propylene oxide adducts have been suggested for vinyl – resin adhesives [121].

5.3.6. Detergents

Polyphosphates are used in the detergent industry, but they are being increasingly replaced by other additives. In Switzerland, for example, the use of detergents was restricted to those free of phosphates from 1986. Substitutes are, for example, zeolites and nitrilotriacetic acid [120]. The addition of optical brighteners is also rejected because they are difficult to degrade in lakes, rivers, and other bodies of water.

5.3.7. Photographic Industry

The coating solutions and dispersions manufactured in the photographic industry contain microcrystals of silver halides dispersed in gelatin (Fig. 14).

Figure 14. Silver halide microcrystals in a photographic "emulsion" [122]

The wetting agents, antistatic agents, and lubricants added must not alter the original properties of the silver halide microcrystals, but on the contrary, they should result in uniform and faultless film formation on various backings such as paper or photographic film. Therefore, careful choice and precise measurement of the quantity are indispensable.

The oldest and most well-known photographic *wetting agent* is the natural product saponin, which despite variations in the quality of the starting material (quillaia bark) has not yetbeen completely displaced because of its good wetting properties and photographic neutrality. Synthetic anionic surfactants contain sulfate, sulfonate, or carboxylic groups as hydrophilic groups (e.g., fatty acid sulfates, alkylarylsulfonates, sulfosuccinic acid derivatives). On the other hand, nonionic wetting agents contain alkyl or alkylaryl groups (often with several alkyl chains containing a total of 8 – 18 carbon atoms) as hydrophobic groups and ester – ether – amide or polyethylene – glycol groups as the hydrophilic part (e.g., polyhydric alcohols, glycerol, sorbitol, and sugar). Perfluorinated surfactants such as Bayer FT 248 have proved to be successful for use with modern multilayer pourers and backing speeds of ≥ 100 m/min.

Antistatics are used in photographic manufacturing to prevent the disadvantages associated with electrical charging, such as inadvertent exposure or attraction of dust. Readily hydratable ionic surfactants such as sulfated alcohols or sulfosuccinic acid esters are used, as are betaines, amine oxides, or short-chain alkyl polyglycol ethers.

Lubricants ensure satisfactory film running in cameras and projectors. They consist of dispersions, for example, of stearic acid, wax, polyethylene, or silicon oil, which are added as oil-in-water emulsions to the uppermost layer of the material. Short-chain alkyl polyglycol ethers are used. Since a number of antistatic agents and lubricants cause faults in the uniformity of the pouring, anionic wetting agents must be added.

In addition, color components that couple to the dyes during photographic development must also be dispersed because they are generally insoluble in gelatin. Alkylsulfonates, condensed sulfonates, sulfated fatty acid amides, or alkylnaphthalene sulfonates are used. Additions of saponin and nonionic surfactants have been described [123].

5.3.8. Agriculture

Dispersants are used to prevent caking in the manufacture of fertilizers. They also ensure uniform distribution of mineral fertilizers in the soil. For these purposes, solid fertilizers are

sprayed with dilute solutions of ethoxylated alcohols, alkylbenzenesulfonates, or occasionally solutions of cationic surfactants.

In plant protection and in pest control, dispersable powders and concentrated suspensions are used [70, p. 394; 119, p. 182]. *Wettable powders* contain the active ingredient, fillers such as kaolin or calcite, dispersants such as ligninsulfonate, sulfonates of condensed aromatic compounds or polyglycol ethers of condensed phenols, and wetting agents such as alkylnaphthalene sulfonate. The powders are manufactured by dry grinding the thoroughly mixed constituents to a particle size of 5 – 40 µm. Grinding additives such as kieselgur or synthetic silica prevent sticking and clotting. Concentrated *suspensions* usually contain 30 – 50 % solids. Mixtures of dispersants and emulsifiers have proved to be suitable for such suspensions, which must remain stable for over 2 years under a wide variety of storage conditions. The suspensions are generally manufactured by wet grinding to a particle size of < 5 µm.

5.3.9. Cosmetic and Pharmaceutical Industry

To manufacture ointment bases of the water-in-oil type, sorbitan fatty acid esters are used, whereas the preparation of an ointment base of the oil-in-water type that can be washed off involves ethoxylated stearic acid or ethoxylated sorbitan fatty acid esters, often mixed with nonethoxylated esters.

Stearic acid and its sodium salt can be dispersed by using mixtures of sorbitan fatty acid esters and their ethoxylated products, as well as with ethoxylated alcohols or fatty acids [110].

Partial fatty acid esters or their ethoxylated products are common in the dispersion of fats. Polyglycol ethers of fatty alcohols and fatty acids and of lanolin or propylene glycol are also used. In addition, mixtures of anionic and nonionogenic emulsifiers are used, as are mixtures of purely nonionic interface-active substances with various HLB values. Lanolin is usually emulsified with fatty alcohol polyglycol ethers. Sulfated esters such as "turkey-red oil" are added to dental care products and, in addition to their dispersive action, are intended to prevent tartar formation.

5.3.10. Cleaning and Polishing Agents

The dispersal of polishing and scouring powders is usually promoted by adding polycyclic aromatic sulfonates; Tamol N brands are suitable for this purpose [93].

5.4. Testing

Since dispersants are used in various industries, the fact that there are no generally applicable test methods is not surprising. The published test methods are usually directed at a special field of application. The following methods exist.

Zinc Oxide Test. The zinc oxide test gives an initial indication of whether inorganic materials are dispersed; however, this test is either not applicable or applicable only with restriction to dye dispersions.

After the dispersant to be tested (3 g) has been shaken with 10 g of zinc oxide in a measuring cylinder containing 200 mL of water, the settling of the zinc oxide is observed and assessed. The settling can be recorded photometrically.

Flocculation Preventing Power [124]. The determination of the flocculation preventing power is based on precipitation of an insoluble compound by a chemical reaction and subsequent determination of the concentration of a dispersant that just prevents the flocculation of the insoluble compound. The standard DIN 53 903 specifies the determination of the ability to disperse calcium soap. The result is given as a percentage of pure sodium oleate, and the flocculation preventing power is inversely proportional to the quantity of dispersant necessary to disperse lime soap [125].

The standard DIN 53 908 specifies the determination of dispersive power with respect to dyes. This involves the precipitation of an insoluble dye from a solution of a leuco ester of a vat dye in the presence of a defined quantity of the surfactants to be tested. Conclusions are drawn about the dispersive action of the material from the quantity of dispersant necessary to achieve a stable dispersion. The stability of the dispersion is assessed from the spreading pattern that results when a defined quantity of the dye dispersion is applied to a dry filter paper [58].

Filtration Methods. Filtration methods also yield information on the stability of dispersions in dyeing processes.

Thus, for example, 250 mg of a commercial dye (C.I. Disperse Red 54) is dispersed in 500 mL of water by adding the dispersant and subsequently treated for 30 min at 125 °C in a laboratory dyeing apparatus. The dispersions are then cooled to 80 °C, filtered by suction through a filter paper (e.g., Schleicher & Schüll No. 1450 CV) and placed on a vacuum filter of 90 mm diameter [69, p. 517]. As less dye remains on the filter, the dispersive power is better.

Spot Test. The filter paper spot test, the so-called *flow test,* can be used as a rapid test for the finenese of a pigment dispersion and, consequently, for the effectiveness of a dispersant. A small amount of the pigment dispersion is dropped onto a piece of filter paper, and the pattern that is produced as the drop spreads is assessed. If the dispersion is fine, the drop spreads uniformly, and as the edge is sharper, the finenese of the dispersion is poorer [69, p. 517].

Practical Test Methods. Standard dyeings in laboratory dyeing apparatuses can be used to determine the effect of dispersants on levelness and rubbing fastness in the printing and thermosol dyeing of fabrics [107]. In addition to these practical test methods, physical methods are being used increasingly to determine the particle size and distribution.

Physical Test Methods. The preparation of electron micrographs [126–128] that can be counted yields the particle size distribution of a dispersion [53], [93], [94], as does sedimentation analysis under gravity and in a centrifugal field [107], [118], [127], [129]. Gravity covers particles of up to 1 µm diameter and the particle size of the disk centrifuge ranges between 0.1 and 10 µm [130]. Counts made with the Coulter counter [130] or optical methods, such as light scattering measurements or laser correlation spectroscopy, are suitable for determining the average particle size or the particle size distribution.

1. Introduction

The "information age" and its enabling technologies will greatly influence our future daily life in the next decades. The electronic provision of information is the backbone of the new age. The human eye is the most versatile sensing organ, easily being able to handle huge data streams either in sequence (e.g., written text) or in parallel (e.g., pictures). The transformation of electronically generated information into specially configured visible signals is carried out by a display device.

An electronic display device consists of several components (Fig. 1). First, there are the electro-optic display elements, which modify their optical appearance by the action of an electrical signal. The electrical information is usually processed by some logic and amplified before it activates the display elements. Sometimes these elements must be backed up by external power sources. In many cases, ancillary elements are added to make detection of the displayed information easier.

The display device is the visual interface between user and machine. Two requirements are placed on this interface: (1) optimum correspondence of the signals generated from the electro-optic display element to the physiological sensory requirements of the human eye and (2) their

adaptation to the requirements of the subsequent neural signal processing for easy interpretation and minimum reading error. Accordingly, display development is of an interdisciplinary nature, including physiology, engineering, optics, materials science, and computer science. The emphasis in this article is on technology, i.e., the engineering and materials science aspects of electronic display devices.

Figure 1. Structure of an electronic display device. The area enclosed by the dashed lines is the display unit.

2. Display Categories

A multitude of very different displays is already available on the market. For structuring this complexity at least three criteria have been put forward to categorize display devices.

The first is a classification according to the *information content* of the display device, which implicitly also largely determines the application area of the display. The information content is related to the number of picture elements (pixels) available. A technically meaningful upper limit for the number of pixels per inch (ppi) or centimeter (ppc) is given by the minimum angle of resolution of the eye. The average naked eye is not able to resolve pixels less than about one minute of arc apart. For a typical computer-screen viewing distance of about 50 cm this means that the meaningful lower limit for the pixel pitch is about 0.15 mm or 170 ppi (67 ppc). (Note that for present automatic bonding processes for connecting external circuitry to the display rows and columns, 130 ppi is the upper limit for production scale.) Figure 2 plots the total number of pixels versus panel size, and includes the areas of different applications, from cellular phone displays via handheld computers and portable TV, e-books, web pads, notebooks and desktop monitors, workstations, large TVs, to large-area professional applications with more than 30 diagonal inches. Pixel formats of panels are often referred to in terms of standardized sets such as VGA (640×480), XGA (1024×768), and UXGA (1280×1600). Note that for colored displays "pixel" always means a entity of the three (red, green, and blue) subpixels; hence, the number of individual subpixels is three times that of simple black and white dislays. Once the pixel format is given, the panel size is determined by the resolution, i.e., the pixel pitch or the number of pixels per inch (or centimeter). Figure 2 includes plots for three high to ultrahigh resolutions.

The second classification is based on the *method of addressing*. In low-information-density displays, e.g., numerical seven-segment displays, each picture element can be addressed individually. In displays with medium-to-high information contents, two addressing techniques allow many picture elements to be addressed in a short time: (1) scanned displays and (2) matrix displays. In the first, the viewing screen is scanned by an electron beam or a light beam that is modulated to produce the desired pattern. The most prominent scanned display is the cathode ray tube. In the second, the display screen is made up of a two-dimensional matrix of pixels, and the pattern is obtained by activating each individual element electrically. In most cases, activation is carried out line by line: all pixels in one line are addressed and activated by the

Figure 2. Different application fields require matched panel sizes. For a given standard pixel format, the size of the panel is determined by the resolution required.

signal on their respective intersecting column. One line after another is activated to build up the image within the frame time. Liquid crystal displays and the vast majority of all other flat panel displays are matrix displays.

The third classification is based on the *method and technology of presenting the information*: (1) off-screen, (2) projection, and (3) direct-view display devices (Fig. 3). *Off-screen* devices include those in which the image does not appear on a screen, but rather is perceived to exist in space as a real or a virtual image. Examples are holographic displays, "head-up" displays, and displays which generate the image directly on the retina of the eye. *Projection displays* include all those that use a viewing screen separate from the optical image source. Currently, projection displays are used primarily when a group of people or a larger audience must be informed or entertained. In *direct-view displays*, the image is generated at, or very close to, the viewing surface of the device. Direct-view devices are the most common display devices.

A prominent direct-view display device is the *cathode ray tube* (CRT), which was the first electronic device to produce images. A great variety of CRTs was invented in the last 100 years, but the basic mechanism of operation is the same in all devices. The quality of images produced by CRTs has been accepted widely as a standard. However, CRTs are large, deep, heavy, and require high voltage.

The desire for portable electronic display devices with the same visual performance as the CRT but without its drawbacks has fuelled a multibillion-dollar industry in the last two to three decades. In 2000 roughly half of the worldwide display sales of about $\$ 52 \times 10^9$ were for flat panel displays, of which liquid crystal displays (LCDs) accounted for close to 90 %. Of growing importance are a number of other new technologies which also provide *flat panel displays*. The technological development in this field is still very dynamic. For 2005 a total revenue of roughly $\$ 100 \times 10^9$ is expected for all types of display modules[11]. Since the compound annual growth rate for flat panel displays is expected to be about four times larger than the growth rate for CRTs, the market share of flat panel products in 2005 is expected to be ca. 63 % of the total market.

Many physical and chemical effects have been explored for their utility in flat panel information presentation. Figure 3 classifies them as emissive or nonemissive technologies. The strong dominance of LCD technologies is expected to persevere until at least 2010, although emissive technologies such as plasma and organic light emitting diodes (LEDs) are expected to gain important market shares.

Figure 3. Categorization of electronic information displays according to the way of viewing the display and the required enabling technologies

3. Cathode Ray Tubes (CRTs)

Cathode ray tubes (CRTs) are the oldest display devices. In 1896, Ferdinand Braun invented a device that already contained all the elementary features of modern CRTs. A monochrome CRT basically consists of an evacuated bulb, an electron gun, a beam-focusing and -deflection system, and a phosphor screen laid on the front face of a sealed bulb. The pressure inside the bulb is usually less than 10^{-5} Pa. In most cases, the bulb is made of glass. The electron gun provides a high-density electron beam, which can be focused and deflected to address any desired point on the phosphor screen. The faceplate carries a thin layer of phosphor particles which emit light under electron bombardment. Usually this layer is covered by a thin layer of aluminum to establish the electrical potential at the screen and to reduce charging effects. The faceplate may be treated specially to improve display contrast, e.g., with an antireflective coating.

3.1. Color CRTs

Color is incorporated into the CRT by providing separate phosphor dots or stripes to generate the three primary colors – red, green, and blue – on the screen (Fig. 4). Proper addressing of these dots is achieved with the aid of a metal mask containing aperture holes or slots. The thickness of the masks varies between 25 and 250 μm, and they are made from low-carbon steel or, in high-end applications, from iron – nickel alloy. Depending on the mass fabrication technology the mask material is either drawn with a pressing tool beyond the yield point to obtain plastic deformation for acquiring a prescribed curved contour, or the mask is welded to a frame that results in tension in the mask material. The latter technology requires strong and therefore heavy frames [13]. The shadow mask in its frame is positioned close to the screen. Three electron beams emanating from electron guns positioned close to the longitudinal axis of the tube in delta or "in-line" configuration. These beams are individually modulated for the three primary colors.

If one gun is regarded as a point source of light, a shadow of the aperture mask falls on the inside of the faceplate. At the same time illuminated dots of the specific color appear on the screen. Arranging the three guns in a symmetrical triangle around the longitudinal axis produces a set of three illuminated dots on the faceplate, one for each primary color. The positions of the three phosphor dots on the screen must fit the shadow mask. This distribution can actually be fabricated in a self-aligned technique that uses the shadow mask during the photolithographic steps for phosphor deposition.

Shadow masks were introduced into large-scale production in 1954 (see, e.g., [15]). Substantial improvements followed and resulted in a strong increase in CRT screen brightness.

Figure 4. Triangular (delta) dot system (A) compared with the in-line system (B), showing the beam paths and the screen structures (after [14])
R = red; G = green; B = blue
Courtesy of the Society for Information Display

Figure 4 B shows a shadow-mask CRT with an in-line configuration of the three electron guns, slot apertures in the shadow mask, and continuous vertical phosphor lines on the screen. This technology allows for larger deflection angles, improved beam convergence, and better resolution, and has been further refined by using strip masks.

To obtain a perfect picture, severe requirements must be imposed on the tube design. Focal and color purity must be maintained, as well as mechanical tolerances, which must be kept low. When the tube is operated, ca. 75 – 80 % of the electron beam is intercepted by the dotted shadow mask. This substantially reduces the brightness and causes heating. In a typical receiver, ca. 35 W is absorbed by the mask and converted to heat. The resulting expansion of the mask must be counteracted by sophisticated bimetal support elements that keep the expanding mask aligned to the electron beam.

3.2. Electron Optics

Figure 5 shows three important processes taking place in the neck of the CRT: (1) beam formation, (2) focus, and (3) deflection.

Electrons escape from the heated cathode surface and are accelerated by the positive potential on grid 2. Application of an appropriate negative potential to grid 1 controls the electron beam intensity. Cathode design is important because CRT lifetime is governed mainly by *cathode life*.

Two cathode configurations are depicted. Figure 5 A shows the conventional oxide cathode, while Figure 5 B shows the dispenser cathode. The *oxide cathode* consists of a barium – strontium oxide layer 10 – 20 µm thick applied to the capped end of a nickel cylinder. The heavy metal oxide reduces the work function of the surface and increases electron emission. In practice, a 10 000-h cathode lifetime is achieved. In the *dispenser cathode*, the barium compound diffuses through a porous tungsten structure to the surface and ensures that the barium content at the surface is replenished, allowing for a much longer lifetime.

As shown in Figure 5, the electron beam can be focused electrostatically or magnetically.

Figure 5. Schematic presentation of the beam forming (I), focusing (II), and deflection (III) regions in the CRT neck
A) Normal oxide cathode with electrostatic focusing and deflection; B) Dispenser cathode with magnetic focusing and deflection systems

Magnetic focusing provides the highest resolution, because magnetic lenses have fewer aberrations than electrostatic lenses. Likewise, deflection can be electrical or magnetic. Electrostatic deflection requires two sets of metal plates (for x and y deflection) set at right angles to each other. Magnetic deflection employs two pairs of coils, the coils in each pair being located on opposite sides of the neck of the tube to provide orthogonal magnetic fields. Electrostatic deflection provides the highest deflection speed but only moderate resolution. Magnetic deflection provides lower deflection speed, but gives satisfactory resolution, especially when combined with electrostatic focus. This combination of magnetic deflection and electrostatic focusing is used widely in television and computer terminal tubes. Magnetically deflected and focused tubes provide the highest resolution.

3.3. Phosphors

The production of visual images from the electronic signals occurs at the phosphor-covered faceplate (→ Luminescent Materials). Table 1 lists the three RGB phosphors mainly used in CRTs with their composition, peak wavelength, decay time, and luminous efficiency.

The *luminous efficiency* of many phosphors (ratio of luminous flux to incident energy) in-

Table 1. Selected phosphors for CRTs

Composition	Peak wavelength, nm	Decay time to 10 % level, ms	Luminous efficiency, lm/W	CIE color coordinates *x,y*
ZnS : Ag	440	25	35 – 60	0.15, 0.06
ZnS – CdS : Ag	530	60	40 – 65	0.32, 0.60
Y_2O_2S:Eu	627	900	30 – 50	0.66, 0.35

creases with the beam energy, tending to saturate only between 15 and 30 kV. For maximum efficiency, CRTs are operated at ca. 20 kV. Luminous efficiency is also affected by current density, usually decaying strongly above 30 mA/cm^2. Under normal operating conditions, luminous efficiencies of phosphors range between 20 and 70 lm/W. The power required by the filament reduces these figures by ca. 30 %. The luminous efficiency of the system takes into account all power necessary to drive the display: on average, 15 lm/W for monochrome CRTs and 6 lm/W for color television.

The luminance of all phosphors decreases under continued electron bombardment. The *decay of efficiency* with the number of coulombs deposited is different for each phosphor. After cathode aging, phosphor aging is the most important factor affecting the CRT lifetime.

3.4. Trends

CRT technology is very mature, and manufacturing costs for commodity parts are relatively low. Typically, materials costs constitute about 65 % of the overall cost in CRT production. The price reduction for color CRTs has been comparatively moderate in the last decades: 30 % for TV tubes and 50 % for color monitor tubes between 1990 and 2000 [17].

In 1997 real-flat TV tubes were first introduced on the market. In theses CRTs the outside surface of the faceplate is practically flat, whereas the inner surface is curved to accommodate the curved mask. Some effort has still to be made to overcome transmission losses associated with the fact that in these faceplates the glass at the corners is much thicker than in the center of the faceplate [18], [19].

4. Flat Panels and Matrix Addressing

The term *flat panel display* essentially covers all the technologies in Figure 3 for non-CRT direct-view display. Flatness in this context usually means that the ratio of device depth to screen diagonal length is less than 1:10, including driving circuitry boards.

Nearly all flat panel designs rely on a matrix arrangement of the picture elements. This has important consequences common to all types of flat panels. Normally, each picture element has one electrode connected to all other picture elements in a row, and the second electrode is connected to all other picture elements in the orthogonal column. When a picture element is selected, its row and column leads are energized to generate a potential across the desired picture element. Analysis of such a network with Kirchhoff's voltage and current laws shows that the minimum potential across all the Off picture elements is one-third of that across the On picture elements because there are three sets of parallel branches between the *x* and *y* terminals of the selected On picture element [20].

The 1/3 voltage is the minimum inherent and unavoidable cross-coupling in matrix addressing. This cross-coupling potential partially excites the display medium. If the luminance – voltage relationship for the picture element is linear, then an image background is seen, impairing the contrast. Therefore, strongly nonlinear luminance – voltage dependence is mandatory for matrix addressing.

Another problem arises from addressing two picture elements of different columns and rows simultaneously. Two additional picture elements light up, and together with the addressed picture elements they formcorners of the rectangle given by the intersection of the two rows and columns.

The addressing of unwanted picture elements is avoided by a *line-at-a-time addressing* technique, in which only one line lead is addressed at any instant. All column leads are addressed

in parallel. With this scheme the Off picture element is excited by 1/3 voltage cross-coupling each time a line is addressed. The On picture element is excited to full On only when its line is addressed and is excited to 1/3 voltage cross-coupling every time the other rows are addressed.
